FEEDBACK LOOPS

A Guide to Feedback Loops Art

Throughout Rosenberg and Kosslyn's *Abnormal Psychology*, you will find discussions of "feedback loops," highlighting the way neurological, psychological, and social factors interact to contribute to psychopathology. *Feedback Loops* icons and *Feedback Loops* figures accompany this coverage.

Feedback Loops Icons

You will see feedback loops icons in the margin of a page next to a discussion of the feedback loop for a particular psychopathology-related phenomenon.

Feedback Loops Icons

- Make it easy to locate discussions of the interplay of different factors for a specific type of psychopathology
- Indicate with boldfaced initials which factors—**N**eurological, **P**sychological, **S**ocial—are associated with a given psychological disorder.

Researchers have also discovered ethnic differences in how patients perceive critical and intrusive family behaviors. Among black American families, for instance, behaviors by family members that focus on problem solving are associated with a better outcome for the schizophrenic individual, perhaps because the behavior is interpreted as reflecting caring and concern (Rosenfarb, Bellack, & Aziz, 2006). Thus, what is important is not the family behavior *in and of itself*, but how such behavior is perceived and interpreted by family members.

- Indicate with outer arrows which factors—**N**eurological, **P**sychological, **S**ocial—are directly targeted by a given treatment.
- Indicate with **boldfaced** initials which other factor(s) are most directly affected—through feedback loops—by a particular treatment.

IPT thus is designed to improve current relationships and social functioning in general. Although IPT was originally developed to treat depression, the idea behind IPT for eating disorders is that as problems with relationships resolve, symptoms decrease, even though the symptoms are not addressed directly by the treatment (Swartz, 1999; Tantleff-Dunn, Gokee-LaRose, & Peterson, 2004).

How does IPT work? The hypothesized mechanism is as follows: (1) IPT reduces longstanding interpersonal problems; and (2) the resulting improvement of relationships makes people feel hopeful and empowered, and increases their self-esteem. These changes have four effects: First, they lead people to change other aspects of their lives, such as disordered eating; second, they lead to less concern about appearance and weight, and therefore less dieting and bingeing (Fairburn, 1997); third, as relationships improve, people have more social contact and hence less time to engage in disordered eating behaviors; and finally, with less interpersonal stress, people don't need to expend as much effort on coping and have less need for bingeing and purging to manage their (less frequent) negative feelings.

Feedback Loops Figures

At the end of the “Understanding” and the “Treating” sections for each major disorder in the edition, you will usually find a Feedback Loops capstone section—e.g., *Feedback Loops in Action: Understanding Schizophrenia* and *Feedback Loops in Treatment: Schizophrenia*—which include figures that illustrate how feedback loops work and the interactions among the various factors.

Feedback Loops in Action Figures

- Summarize the neurological, psychological, and social factors that are associated with a given disorder
- Illustrate the dynamic interactive nature of the factors
- Provide a recurring illustrative format, which allows students to compare and contrast the specific factors of the feedback loops across disorders

Figure 12.5

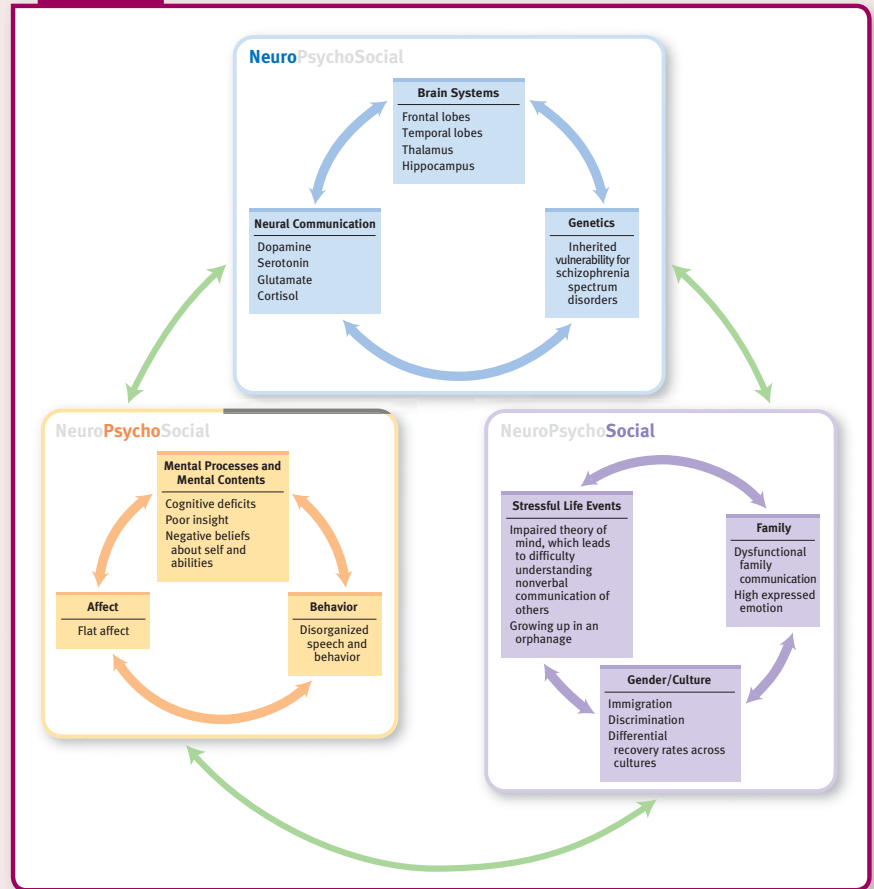

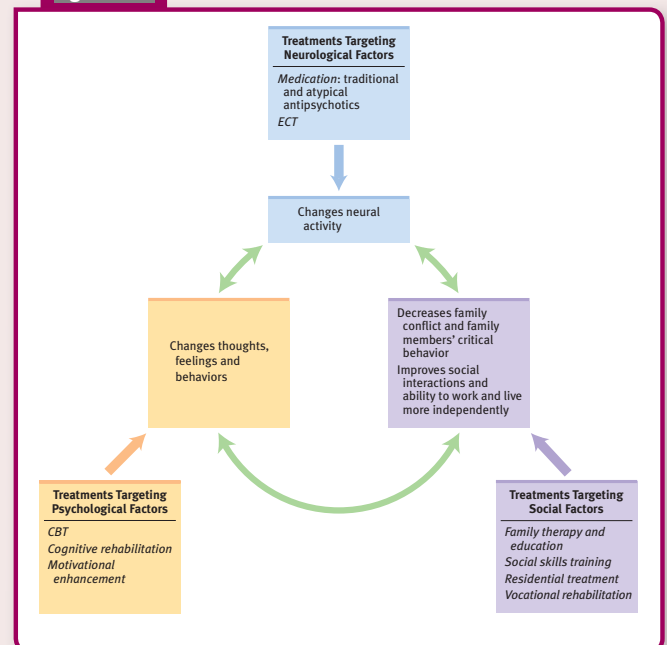

Figure 12.6

Feedback Loops in Treatment Figures

- Summarize the neurological, psychological, and social treatments for a given disorder
- Illustrate the interactive nature of successful treatment
- Provide a recurring illustrative format, which allows students to compare and contrast the specific factors involved in treatment feedback loops across disorders

ABOUT THE AUTHORS

Robin S. Rosenberg is a clinical psychologist in private practice and has taught psychology courses at Lesley University and Harvard University. In addition, she is coauthor (with Stephen Kosslyn) of *Psychology in Context* and *Fundamentals of Psychology in Context*. She is the editor of *Psychology of Superheroes* and a contributor to *The Psychology of Harry Potter* and *Batman Unauthorized*. She is board certified in clinical psychology by the American Board of Professional Psychology, and has been certified in

clinical hypnosis; she is a fellow of the American Academy of Clinical Psychology and a member of the Academy for Eating Disorders. She received her B.A. in psychology from New York University and her M.A. and Ph.D. in clinical psychology from the University of Maryland, College Park. Dr. Rosenberg completed her clinical internship at Massachusetts Mental Health Center and had a postdoctoral fellowship at Harvard Community Health Plan before joining the staff at Newton-Wellesley Hospital's Outpatient Services, where she worked before leaving to expand her private practice. Dr. Rosenberg specializes in treating people with depression, anxiety, and eating disorders, and she is interested in the integration of different therapy approaches. She was the founder and coordinator of the New England Society for Psychotherapy Integration. Dr. Rosenberg enjoys using superhero stories to illustrate psychological principles and can sometimes be found at comic book conventions.

Stephen M. Kosslyn is the John Lindsley Professor of Psychology and former chair of the Department of Psychology at Harvard University, as well as former Head Tutor (directing the undergraduate program in Psychology). He currently is Dean of Social Science at Harvard as well as Associate Psychologist in the Department of Neurology at the Massachusetts General Hospital. He received a B.A. from UCLA and a Ph.D. from Stanford University, both in psychology.

His research has focused primarily on the nature of visual mental imagery, visual perception, and visual communication; he has authored or coauthored 9 books and over 300 papers on these topics. Kosslyn has received the APA's Boyd R. McCandless Young Scientist Award, the National Academy of Sciences Initiatives in Research Award, the Cattell Award, a Guggenheim Fellowship, the J-L. Signoret Prize (France), and an honorary Doctorate of Science from the University of Caen (France), and he has been elected to Academia Rodinensis pro Remediatione (Switzerland), the Society of Experimental Psychologists, and the American Academy of Arts and Sciences. Kosslyn works hard, but not every waking moment; his hobbies are bass guitar (he has played rock-and-roll and blues with the same group for many years) and French (he has struggled with the language ever since living in France for a year in 1996).

This is an exciting time to study psychopathology. Research on the entire range of psychological disorders has blossomed during the last decade, yielding new insights about psychological disorders and their treatments. However, the research results are outpacing the popular media's ability to explain them. We've noticed that when study results are explained in a television news report or a mainstream magazine article, "causes" of mental illness are often reduced to a single factor, such as genes, brain chemistry, irrational thoughts, or social rejection. But that is not an accurate picture. Research increasingly reveals that psychopathology arises from a confluence of three types of factors: *neurological* (brain and body, including genes), *psychological* (thoughts, feelings, and behaviors), and *social* (relationships and communities). Moreover, these three sorts of factors do not exist in isolation, but rather mutually influence each other.

We are a clinical psychologist (Rosenberg) and a cognitive neuroscientist (Kosslyn) who have been writing collaboratively for many years. Our observations about the state of the field of psychopathology—and the problems with how it is sometimes portrayed—led us to envision an abnormal psychology textbook that is guided by a central idea, which we call the *neuropsychosocial approach*. This approach allows us to conceptualize the ways in which neurological, psychological, and social factors interact to give rise to mental disorders. These interactions take the form of feedback loops in which every type of factor affects every other type. Take depression, for instance, which we discuss in Chapter 6: Someone who attributes the cause of a negative event to himself or herself (such attributions are a psychological factor) is more likely to become depressed. But this tendency to attribute the cause of negative events to oneself is influenced by social experiences, such as being criticized or abused. In turn, such social factors can alter brain functioning (particularly if one has certain genes), and abnormalities in brain functioning affect social interactions, and so on—round and round.

The neuropsychosocial approach grew out of the venerable biopsychosocial approach; instead of focusing broadly on biology, however, we take advantage of the bountiful harvest of findings about the brain that have filled the scientific journals over the past two decades. Specifically, the name change signals a focus on the brain itself; we derive much insight from the findings of neuroimaging studies, which reveal how brain systems function normally and how they have gone awry with mental disorders, and we also learn an enormous amount from findings regarding neurotransmitters and genetics.

Although mental disorders cannot be fully understood without reference to the brain, neurological factors alone cannot explain these disorders; rather, mental disorders develop through the complex interaction of neurological factors with psychological and social factors. We argue strongly that psychopathology cannot be reduced to "brain disease," akin to a problem someone might have with his or her liver or lungs. Instead, we show that the effects of neurological factors can only be understood in the context of the other two types of factors addressed within the neuropsychosocial approach. Thus, we not only present cutting-edge neuroscience research results but also put them in their proper context. (In fact, an understanding of a psychological disorder cannot be reduced to *any* single type of factor, whether genetics, irrational thoughts, or family interaction patterns.)

Our emphasis on feedback loops among neurological, psychological, and social factors led us to reconceptualize and incorporate the classic diathesis-stress model. In the classic view, the diathesis was almost always treated as a biological state, and the stress was viewed as a result of environmental events. In contrast, after describing the conventional diathesis-stress model in Chapter 1, we explain how the neuropsychosocial approach provides a new way to think about the relationship between diathesis and stress. Specifically, we show how one can view any of the

three sorts of factors as a potential source of either a diathesis (a precondition that makes a person vulnerable) or a stress (a triggering event). For example, living in a dangerous neighborhood, which is a social factor, creates a diathesis for which psychological events can serve as the stress, triggering an episode of depression. Alternatively, being born with a very sensitive amygdala may act as a diathesis for which social events—such as observing someone else being mugged—can serve as a stressor that triggers an anxiety disorder.

Thus, the neuropsychosocial approach is not simply a change in terminology (“bio” to “neuro”), but rather a change in basic orientation: We do not view any one sort of factor as “privileged” over the others, but regard the interactions among the factors—the feedback loops—as paramount. In our view, this approach incorporates what was best about the biopsychosocial approach and the diathesis-stress model. The resulting new approach led naturally to a set of unique features, as we outline next.

Unique Coverage

Through its integration of cutting-edge neuroscience research and more traditional psychosocial research on psychopathology and its treatment, this textbook provides students with a sense of the field as a coherent whole, in which different research methods illuminate different aspects of abnormal psychology. Our integrated neuropsychosocial approach allows students to learn not only how neurological factors affect mental processes (such as memory) and mental contents (such as distorted beliefs), but also how neurological factors affect emotions, behavior, social interactions, and responses to environmental events. And further, the approach allows students to learn how neurological, psychological, and social factors affect each other.

The 16 chapters included in this book span the traditional topics covered in an abnormal psychology course. The neuropsychosocial theme is reflected in both the overall organization of the text and the organization of its individual chapters. We present the material in a decidedly contemporary context that infuses both the foundational chapters (Chapters 1–5) as well as the chapters that address specific disorders (Chapters 6–15).

In the chapter that provides an overview of explanations of abnormality (Chapter 2), neurological, psychological, and social factors are discussed as etiological factors. Our coverage is not limited merely to categorizing causes as examples of a given type of factor; rather, we explain how events pertaining to a given type of factor influence and create feedback loops with other factors. Consider depression again: The loss of a relationship (social factor) can affect thoughts and feelings (psychological factors), which—given a certain genetic predisposition (neurological factor)—can trigger depression. Using the neuropsychosocial approach, we show how disparate fields of psychology and psychiatry (such as neuroscience and clinical practice) are providing a unified and overarching understanding of abnormal psychology.

Our chapter on diagnosis and assessment (Chapter 3) uses the neuropsychosocial framework to organize methods of assessing abnormality. We discuss how abnormality may be assessed through measures that address the different types of factors: neurological (e.g., neuroimaging data or lab tests, and we note that even measures taken from the blood ultimately reflect brain events), psychological (e.g., clinical interviews, questionnaires, or inventories), and social (e.g., family interviews or a history of legal problems).

Similarly, in the treatment chapter (Chapter 4), we describe treatment from the neuropsychosocial perspective, explaining how each type of treatment is designed to target and change specific factors (e.g., medications aimed at neurotransmitter levels, cognitive-behavior therapy that focuses on thoughts and behaviors, or family therapy that addresses family interactions). We also explain how successful treatment—of any type—affects *all* factors, positively influencing neurological functioning, thoughts, feelings, behaviors, and social interactions.

The research methods chapter (Chapter 5) also provides unique coverage. We explain the general scientific method, but we do so within the neuropsychosocial framework. Specifically, we consider methods used to study neurological and other biological factors (e.g., neuroimaging), psychological factors (e.g., self-reports of thoughts and moods), and social factors (e.g., observational studies of dyads or groups or of cultural values and expectations). We show how the various measures themselves reflect the interactions among the different types of factors. For instance, when researchers ask participants to *report* family dynamics, they are relying on psychological factors—participants’ memories and impressions—to provide measures of social factors. Similarly, when the number of items checked off on a stressful life events scale is used to infer the actual stress experienced by individual participants, social and environmental factors are providing a proxy measure of the psychological and neurological consequences of stress. The chapter also discusses research on treatment from the neuropsychosocial framework.

The clinical chapters (Chapters 6–15), which address specific disorders, also rely on the neuropsychosocial approach to organize the discussions of both etiology and treatment of the disorders. Moreover, when we discuss a particular disorder, we address the three basic questions of psychopathology: What exactly constitutes this psychological disorder? How does it arise? How can it be treated?

Pedagogy

All abnormal psychology textbooks cover a lot of ground: Students must learn new concepts, facts, and theories. We want to make that task easier, to help students consolidate the material they learn and to come to a deeper understanding of the material. The textbook uses a number of pedagogical tools to achieve this goal.

Feedback Loops Within the Neuropsychosocial Approach

This textbook highlights and reinforces the theme of feedback loops among neurological, psychological, and social factors in several ways:

- In the “Understanding” sections of each chapter (for instance, “Understanding Panic Disorder”), when two or more types of factors are part of a feedback loop, we explicitly call out these relationships by highlighting the margin in beige where we mention such feedback loops, and include an icon in the margin that notes the specific factors involved. The icon specifies which types of factors and feedback loops are directly implicated by a particular study, set of findings, or theory (“N” for neurological, “P” for psychological, and “S” for social). For instance, in the margin here is the icon we use to note specific evidence or theory that implicates psychological and social factors—and the feedback loop between them—as contributing to a particular psychological disorder.

	<p>Social Factors: Modeling</p> <p>Sometimes, simply seeing other people exhibit fear of a particular stimulus is enough to make the observer become afraid of that stimulus (Mineka, Cook, & Miller, 1984). For example, if as a young child, you saw your older cousin become agitated and anxious when a dog approached, you might well learn to do the same. Similarly, repeated warnings about the dangers of a stimulus can increase the risk of developing a specific phobia of that stimulus (Anthony & Barlow, 2002). After</p>
---	---

- Similarly, in the “Treating” sections of each chapter (for instance, “Treating Panic Disorder”), highlighting and icons in the margin mark the relevant feedback loops. In addition, an arrow points to the type of factor that is the direct target of relevant treatment. (However, we stress that even though one sort of factor is the direct target, it

rarely—if ever—is the only one affected by the therapy.) For instance, below is the icon we use to note when treatment that directly targets a psychological factor in turn can affect neurological factors and create feedback loops between the two kinds of factors.

were afraid of touching dirt, she would touch dirt but would not then wash her hands. Through exposure and response prevention, patients learn that nothing bad happens if they don't perform their compulsive behavior; the anxiety is lessened without resorting to the compulsion, their fear and arousal subside, and they experience mastery. They survived the anxiety and exerted control over the compulsion. When patients successfully respond differently to a feared stimulus, this mastery over the compulsion

- At the end of the “Understanding” and the “Treating” sections, we typically have concluding sections that explicitly call attention to interactions among the three factors and that walk students through a description of how the three types of factors affect one another via feedback loops. Examples of these sections are *Feedback Loops in Action: Understanding Panic Disorder* and *Feedback Loops in Treatment: Panic Disorder*.

FEEDBACK LOOPS IN ACTION: **Understanding Panic Disorder**

Cognitive explanations of panic disorder can help show how a few panic attacks can progress to panic disorder, but not everyone who has panic attacks develops panic disorder. It is only when neurological, biological, and psychological factors interact that panic disorder develops (Bouton, Mineka, & Barlow, 2001). Cognitive processes such as catastrophic thinking and anxiety sensitivity (psychological factors) are triggered, in part, by environmental and social stressors (social factors). Indeed, such stressors may lead an individual to be aroused (neurological factor), but he or she then misinterprets the cause of this arousal (psychological factor). This misinterpretation may increase the arousal (Wilkinson et al., 1998), making it more likely that symptoms of panic—rapid heartbeat or shallow breathing—will follow.

For example, a man's argument with his wife might arouse his anger and

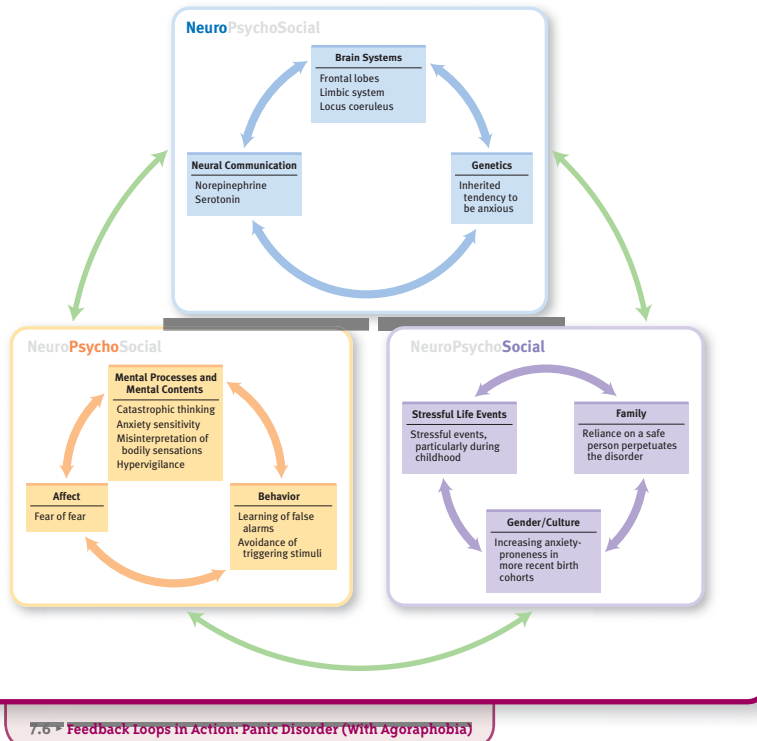

FEEDBACK LOOPS IN TREATMENT: **Panic Disorder**

Invariably, medication—which changes neurological functioning—stops exerting its beneficial effect when the patient stops taking it. The positive changes in neural communication and brain activity, and the associated changes in thoughts, feelings, and behaviors do not endure. Eventually, the symptoms of panic disorder return. For some patients, though, medication is a valuable first step, providing enough relief from symptoms that they are motivated to obtain CBT, which can change their reactions (psychological factor) to perceived bodily sensations (neurological factor). When a patient receives both medication and CBT, however, the medication should be at a low enough dose that the patient can still feel the sensations that led to panic in the past (Taylor, 2000). In fact, the dose should be gradually decreased so that the patient can experience enough anxiety to be increasingly able to make use of cognitive-behavioral methods. It is the CBT that leads to enduring changes: Researchers have found that adding medication to CBT doesn't provide an advantage over CBT alone (de Beurs et al., 1999). This finding has led to CBT's being recommended even for those who prefer medication (Ellison & McCarter, 2002).

With medication, the patient's anxiety is reduced, and successful

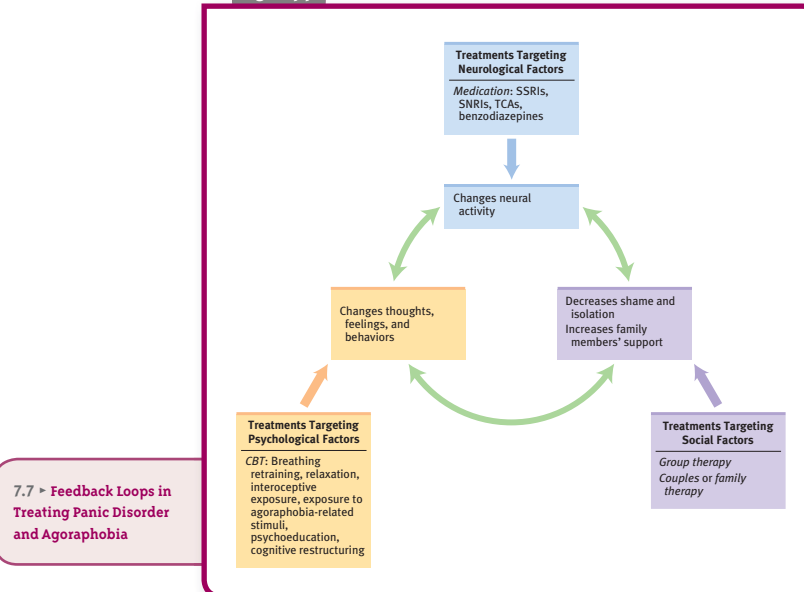

- At the end of most *Feedback Loops in Action* and *Feedback Loops in Treatment* sections, we include a neuropsychosocial “Feedback Loops” figure; this figure illustrates the feedback loops among the neurological, psychological, and social factors.
- The *Feedback Loops in Action* figures serve several purposes: (1) They provide a visual summary of the most important neuropsychosocial factors that contribute to the various disorders; (2) they illustrate the interactive nature of the factors; (3) their overall structure is the same for each disorder, which allows students to compare and contrast the specifics of the feedback loops across disorders.

Figure 7.6

- Like the *Feedback Loops in Action* figures, the *Feedback Loops in Treating a Disorder* figures serve several purposes: (1) The figures provide a visual summary of the treatments for the various disorders; (2) they illustrate the interactive nature of successful treatment, the fact that a treatment may directly target one type of factor but change in that factor in turn affects other factors; (3) their overall structure is the same for each disorder, which allows students to compare and contrast the specifics of the feedback loops across disorders.

Figure 7.7

Clinical Material

Abnormal psychology is a fascinating topic, but we want students to go beyond fascination; we want them to understand the human toll of psychological disorders—what it’s like to suffer from and cope with such disorders. To do this, we’ve incorporated several pedagogical elements. In addition to transcripts of therapy sessions and brief first-person descriptions of particular symptoms, the textbook includes three types of clinical material: a story woven through each chapter, traditional third-person cases (*From the Outside*), and first-person accounts (*From the Inside*).

Chapter Stories: Illustration and Integration

Each chapter opens with a story about an individual (or, in some cases, several individuals) who has symptoms of psychological distress or dysfunction. Observations about the person or people described in the opening story are then woven throughout the chapter. These chapter stories illustrate the common threads that run throughout the chapter (and thereby integrate the material), serve as retrieval cues for later recall of the material, and show students how the theories and research presented in each chapter apply to real people in the real world; the stories humanize the clinical descriptions and discussions of research presented in the chapters.

CHAPTER

6

Mood Disorders and Suicide

Kay Redfield Jamison, a psychologist who studies mood disorders, is uniquely qualified to report and reflect on such disorders. Not only has she made mood disorders her area of professional expertise, but she has also lived with such a disorder. In her memoir, *An Unquiet Mind* (1995), Jamison recounts her experiences. The youngest of three children in a military family, she and her siblings attended four different elementary schools—some in foreign countries—by the time she was in 5th grade. She describes her father, a meteorologist and Air Force officer, as expansive, with infectious good moods, and impulsive, often giving the children gifts. It was “like having Mary Poppins for a father” (Jamison, 1995, p. 17). However, he also suffered periods when he was immobilized by depression, and he generally had trouble regulating his emotions.

As we’ll see in this chapter, Jamison herself developed difficulties regulating her emotions. She recounts that when she was a senior in high school, her mood became so dark that her thinking

... was torturous. I would read the same passage over and over again only to realize that I had no memory at all for what I had just read. Each book or poem I picked up was the same way. Incomprehensible ... I could not begin to follow the material presented in my classes. ... It was very frightening. ... [my mind] no longer found anything interesting or enjoyable or worthwhile. It was incapable of concentrated thought and turned time and time again to the subject of death: I was going to die, what difference did anything make? Life’s run was only a short and meaningless one, why live? I was totally exhausted and could scarcely pull myself out of bed in the mornings. ... I wore the same clothes over and over again, as it was otherwise too much of an effort to make a decision about what to put on. I dreaded having to talk with people, avoided my friends whenever possible, and sat in the school library in the early mornings and late afternoons, virtually inert, with a dead heart and a brain as cold as clay.

(Jamison, 1995, pp. 37–38)

In this passage, Jamison describes problems arising from her *mood*, a persistent emotion lurking in the background, regardless of what is occurring. The category of psychological disorders called **mood disorders** encompasses prolonged and marked disturbances in mood that affect how people feel, what they believe and expect, how they think and talk, and how they interact with others. In any particular year, about 8% of Americans experience a mood disorder (Substance Abuse and Mental Health Services Administration [SAMHSA], 2008). Mood disorders are among the leading causes of disability worldwide (World Health Organization [WHO], 2008).

1 9 1

The chapter stories present individuals as clinicians and researchers often find them—with sets of symptoms: It is up to the clinician or researcher to make sense of the symptoms, determining which of them may meet the criteria for a particular disorder, which may indicate an atypical presentation, and which may arise from a comorbid disorder. Thus, we ask the student to see situations from the point of view of clinicians and researchers, who must sift through the available information to develop hypotheses about possible diagnoses and then obtain more information to confirm or disconfirm these hypotheses.

In the first two chapters, the opening story is about a mother and daughter—Big Edie and Little Edie Beale—who were the subject of a famous documentary in the 1970s and whose lives have been portrayed more recently in the play and HBO film *Grey Gardens*. In these initial chapters, we offer a description of the Beales' lives and examples of their *very* eccentric behavior to address two questions central to psychopathology: How is abnormality defined? Why do psychological disorders arise?

The chapter stories in subsequent chapters focus on different examples of symptoms of psychological disorders, drawn from the lives of other people. For example, in Chapter 7, we discuss the reclusive billionaire Howard Hughes and the football star Earl Campbell, both of whom suffered from symptoms of anxiety; in Chapter 12, we discuss the Genain quadruplets—all four of whom were diagnosed with schizophrenia. To provide a flavor of how we use such stories, here's an example from the beginning of Chapter 13 on personality disorders. The chapter begins like this:

Rachel Reiland wrote a memoir called *Get Me Out of Here*, about living with a personality disorder. In the opening of the book, Reiland remembers Cindy, the golden-haired grade-school classmate who was their teacher's favorite. At the end of a painting class, Cindy's painting was beautiful, with distinctive trees. Unfortunately, Rachel's painting looked like a "putrid blob." Rachel then recounts:

"I seethed with jealousy as Mrs. Schwarzeuser showered Cindy with compliments. Suddenly, rage overwhelmed me. I seized a cup of brown paint and dumped half of it over my picture. Glaring at Cindy, I leaned across the table and dumped the other half over her drawing. I felt a surge of relief. Now Cindy's picture looked as awful as mine.

"'Rachel!' Mrs. Schwarzeuser yelled. 'You've completely destroyed Cindy's beautiful trees. Shame on you. You are a *horrible* little girl. The paint is everywhere—look at your jeans.'

"My blue jeans were soaked with brown paint. They looked ugly. I looked ugly. Mrs. Schwarzeuser frantically wiped up paint to keep it from dripping onto the floor. Everyone was watching.

"I felt my body go numb. My legs, arms, and head were weightless. Floating. It was the same way I felt when Daddy pulled off his belt and snapped it. Anticipation of worse things to come—things I had brought on myself because I was different.

"'In all my years, I've never seen a child like you. You are the *worst* little girl I've ever taught. Go sit in the corner, immediately.'

"Shame on Rachel. That language I understood. And deserved....

"Mrs. Schwarzeuser was right. I was horrible." (Reiland, 2004, pp. 1–2)

We return to Reiland's story throughout Chapter 13, noting when her symptoms resemble those of one personality disorder or another, as well as the ways in which her symptoms may not meet the diagnostic criteria for various personality disorders. The stories in other chapters are handled similarly.

From the Outside

The feature called *From the Outside* provides third-person accounts (typically case presentations by mental health clinicians) of disorders or particular symptoms of disorders. These accounts provide an additional opportunity for memory consolidation of the material, an additional set of retrieval cues, a further sense of how symptoms and disorders affect real people; these cases also serve to expose students to professional case material. The *From the Outside* feature covers an array of disorders, including cyclothymic disorder (Case 6.5) in Chapter 6, panic

disorder (Case 7.2) in Chapter 7, transvestic fetishism in Chapter 11 (Case 11.6), and separation anxiety disorder (Case 14.8) in Chapter 14. Often several *From the Outside* cases are included in a chapter; for instance, in Chapter 8, we include *From the Outside* cases on dissociative amnesia (Case 8.1), dissociative fugue (Case 8.2), depersonalization disorder (Case 8.3), somatization disorder (Case 8.5), and body dysmorphic disorder (Case 8.8).

CASE 12.1 • FROM THE OUTSIDE: Disorganized Schizophrenia

Emilio is a 40-year-old man who looks 10 years younger. He is brought to the hospital, his twelfth hospitalization, by his mother because she is afraid of him. He is dressed in a ragged overcoat, bedroom slippers, and a baseball cap and wears several medals around his neck. His affect ranges from anger at his mother (“She feeds me shit . . . what comes out of other people’s rectums”) to a giggling, obsequious seductiveness toward the interviewer. His speech and manner have a childlike quality, and he walks with a mincing step and exaggerated hip movements. His mother reports that he stopped taking his medication about a month ago and has since begun to hear voices and to look and act more bizarrely. When asked what he has been doing, he says, “eating wires and lighting fires.” His spontaneous speech is often incoherent and marked by frequent rhyming and clang associations (speech in which sounds, rather than meaningful relationships, govern word choice).

Emilio’s first hospitalization occurred after he dropped out of school at age 16 and since

From the Inside

In every chapter in which we address a disorder in depth, we present at least one first-person account of what it is like to live with that disorder or particular symptoms of it. In addition to providing high-interest personal narratives, these *From the Inside* cases help students to consolidate memory of the material (because they mention the symptoms the individual experienced), provide additional retrieval cues, and are another way to link the descriptions of disorders and research findings with real people’s experiences.

CASE 6.1 ► FROM THE INSIDE: Major Depressive Episode

Another experience of depression was captured by the writer William Styron in his memoir, *Darkness Visible*.

In depression this faith in deliverance, in ultimate restoration, is absent. The pain is unrelenting, and what makes the condition intolerable is the foreknowledge that no remedy will come—not in a day, an hour, a month, or a minute. If there is mild relief, one knows that it is only temporary; more pain will follow. It is hopelessness even more than pain that crushes the soul. So the decision-making of daily life involves not, as in normal affairs, shifting from one annoying situation to another less annoying—or from discomfort to relative comfort, or from boredom to activity—but moving from pain to pain. One does not abandon, even briefly, one’s bed of nails, but is attached to it wherever one goes.

(Styron, 1990, p. 62)

The *From the Inside* cases illuminate what it is like to live with disorders such as agoraphobia (Case 7.3), obsessive-compulsive disorder (Case 7.6), hypochondriasis (Case 8.7), alcohol dependence (Case 9.5), gender identity disorder (Case 11.1), schizophrenia (Case 12.2), attention-deficit/hyperactivity disorder (Case 14.7), and dementia (Case 15.4), among others.

Learning About Disorders: Consolidated Tables to Consolidate Learning

In addition to explaining each disorder in the text, we provide two types of tables to help students organize and consolidate information related to diagnosis: DSM-IV-TR diagnostic criteria tables, and *Facts at a Glance* tables.

DSM-IV-TR Diagnostic Criteria Tables

The American Psychiatric Association’s manual of psychiatric disorders—the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision (DSM-IV-TR)—provides tables of the diagnostic criteria for each of the listed disorders. For each disorder that we discuss at length, we present its full DSM-IV-TR diagnostic criteria table so that students become familiar with how the diagnostic criteria are presented in the manual; the criteria—and criticisms of them—are also explained in the text itself.

Table 3.4 ▶ DSM-IV-TR Diagnostic Criteria for Schizophrenia

A. Characteristic symptoms: Two (or more) of the following, with each being present for a significant portion of time during a 1-month period:

- (1) delusions
- (2) hallucinations
- (3) disorganized speech (evidenced by sentences that make no sense because words are scrambled and the thoughts appear disconnected).
- (4) grossly disorganized behavior (including difficulty with daily tasks such as organizing a meal or maintaining proper hygiene).

Note: The first four symptoms are often referred to as *positive* symptoms, because they suggest the *presence* of an excess or distortion of normal functions.

- (5) negative symptoms (which indicate an absence of normal functions), such as a failure to express or respond to emotion; slow, empty replies to questions; or an inability to initiate goal-directed behavior.

Note: Only one Criterion A symptom is required if delusions are bizarre or hallucinations consist of a voice keeping up a running commentary on the person's behavior or thoughts, or two or more voices conversing with each other.

B. Social/occupational dysfunction: Since the disturbance began, one or more major areas of functioning such as work, interpersonal relations, or self-care are *markedly* below the level achieved before the disturbance appeared.

C. Duration: Continuous signs of the disturbance persist for at least 6 months, with at least 1 month of symptoms that meet Criterion A.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision. Copyright 2000 by the American Psychiatric Association. For more information, see the text.

In Chapter 7, for example, full DSM-IV-TR diagnostic criteria tables are included for generalized anxiety disorder, panic attack, panic disorder (with or without agoraphobia), agoraphobia, social phobia, specific phobia, obsessive-compulsive disorder, and posttraumatic stress disorder.

Facts at a Glance Tables for Disorders

An important innovation is summary tables that provide key facts about prevalence, comorbidity, onset, course, and gender and cultural factors for each disorder. These facts are presented in easy-to-read tables, which are titled with the name of the disorder, followed by the term *Facts at a Glance* (for instance, *Obsessive-Compulsive Disorder Facts at a Glance*). These tables give students the opportunity to access this relevant information in one place and to compare and contrast the facts for various disorders.

Table 7.5 ▶ Panic Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none"> Up to 3% of people worldwide will experience panic disorder at some point in their lives (Rouillon, 1997; Somers et al., 2006). However, 30% of people will experience at least one panic attack in their lives. Up to 60% of people seen by cardiologists have panic disorder.
Comorbidity
<ul style="list-style-type: none"> About 80% of people with panic disorder will have an additional Axis I disorder (Ozkan & Altindag, 2005). The two Axis I disorders mostly commonly associated with panic disorder are depression (up to 65% of cases) and substance abuse (up to 30% of cases) (Biederman et al., 2005; Keller & Hanks, 1994; Magee et al., 1996). Approximately 15–30% of those with panic disorder also have social phobia or GAD, and 2–20% have some other type of anxiety disorder (Goisman et al., 1995). Over a third of those with panic disorder also have a personality disorder—an Axis II disorder (Ozkan & Altindag, 2005).
Onset
<ul style="list-style-type: none"> Panic disorder is most likely to arise during two phases of life: the teenage years or the mid-30s.
Course
<ul style="list-style-type: none"> The frequency of panic attacks varies from person to person: <ul style="list-style-type: none"> Some people get panic attacks once a week for months, Others have attacks every day for a week. The frequency of panic attacks can vary over time: <ul style="list-style-type: none"> After having regular panic attacks, a person can experience weeks or even years with less frequent attacks or no attacks at all, Other patients come to have limited-symptom attacks—experiencing fewer than the minimum of four symptoms necessary for a diagnosis of panic attack (see Table 7.3), Some people have no change over time in the frequency of their attacks.
Gender Differences
<ul style="list-style-type: none"> Women are two to three times more likely than men to be diagnosed with panic disorder.
Cultural Differences
<ul style="list-style-type: none"> Symptoms of panic disorder are generally similar across cultures, although people in some cultures may experience or explain the symptoms differently, such as “wind overload” among the Khmer (Hinton et al., 2002, 2003).

Source: Unless otherwise noted, all data are from the American Psychiatric Association.

Summarizing and Consolidating

We include two more key features to help students learn the material: end-of-section reviews and end-of-chapter summaries (called *Summing Up*).

End-of-Section Reviews

At the end of each major section, two types of pedagogical elements help students review the material they have read:

- **Key Concepts and Facts Summary.** This feature uses bulleted lists to summarize the fundamental concepts and facts discussed in the section.

Key Concepts and Facts About Understanding Schizophrenia

- A variety of neurological factors are associated with schizophrenia:
 - Abnormalities in brain structure and function have been found in the frontal and temporal lobes, the thalamus, and the hippocampus. Moreover, certain brain areas do not appear to interact with each other properly. People with schizophrenia are more likely to have enlarged ventricles than are other people. The brain abnormalities give rise to biological markers in some individuals.
 - These brain abnormalities appear to be a result of, at least in some cases, maternal malnourishment or illness during pregnancy or to fetal exposure to certain substances.
- Psychological factors that are associated with schizophrenia and shape the symptoms of the disorder include:
 - cognitive deficits in attention, memory, and executive functioning;
 - dysfunctional beliefs and attributions; and
 - difficulty recognizing and conveying emotions.
- Various social factors are also associated with schizophrenia:
 - an impaired theory of mind, which makes it difficult to understand the behavior of others and to interact with them.

- **Making a Diagnosis.** This feature is designed to help students consolidate the information about diagnostic criteria by applying the criteria to symptoms *as they are expressed in real people*. For each disorder, we ask students to diagnose the

individual in a case that was presented in a *From the Inside* or *From the Outside* section. Students are asked to reread the case carefully and determine which DSM-IV-TR criteria are met and are not met and whether there is enough information to warrant a diagnosis. If the students would like more information in order to make a diagnosis (or to decide whether a diagnosis is not appropriate), we ask them to describe what information—specifically—they want and to explain how it would inform their diagnosis. The *Making a Diagnosis* feature can be used as homework or as a springboard for small-group or class discussions.

Making a Diagnosis

- Reread Case 12.1 about Emilio, and then determine whether or not his symptoms met the minimum criteria for a diagnosis of schizophrenia. Specifically, list which criteria apply and which ones do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision? If you decide that a diagnosis of schizophrenia is appropriate for Emilio, do you think he has the deficit or nondeficit subtype, and why?

End-Of-Chapter Review: Summing Up

The end-of-chapter review, called *Summing Up*, has three elements, each of which is designed to help students further consolidate the material in memory and to foster their critical thinking about the material (which itself furthers learning):

- *Section summaries.* These summaries repeat the important information in the end-of-section summaries, allowing students to review what they have learned in the broader context of the entire chapter's material.

SUMMING UP

Summary of Depressive Disorders

A major depressive episode (MDE) is the building block for a diagnosis of major depressive disorder (MDD); when a person has an MDE, he or she is diagnosed with MDD. Symptoms of an MDE can arise in three areas: affect, behavior, and cognition.

Depression is becoming increasingly prevalent in younger cohorts. Depression and anxiety disorders have a high comorbidity—around 50%. MDD may arise with melancholic features, catatonic features, or psychotic features. Symptoms may also fall into less common patterns, as in atypical depression and chronic depression.

A diagnosis of dysthymic disorder requires fewer symptoms than does a diagnosis of MDD; however, the symptoms of dysthymic disorder must persist for a longer time than do symptoms of MDD. People who have both dysthymic disorder and MDD are said to have double depression.

Neurological factors related to depression include low activity in the frontal lobes, and abnormal functioning of dopamine, serotonin, and norepinephrine. The stress-diathesis model of depression highlights the

Thinking like a clinician

Suppose that a friend began to sleep through morning classes, seemed uninterested in going out and doing things together, and became quiet and withdrawn. What could you conclude or not conclude based on these observations? If you were concerned that these were symptoms of depression, what other symptoms would you look for? What if your friend's symptoms did not appear to meet the criteria for an MDE—what could you conclude or not conclude? If your friend was, in fact, suffering from depression, how might the three types of factors explain the depressive episode? What treatments might be appropriate?

Summary of Bipolar Disorders

The four building blocks for diagnosing bipolar disorders are major depressive episode (MDE), manic episode, mixed episode, and hypomanic episode. Symptoms of a manic episode include grandiosity, pressured speech, flight of ideas, distractibility, poor judgment, decreased need for sleep, and psychomotor agitation. A mixed episode is characterized by symptoms of both an MDE and a manic episode and may include

Social factors that are associated with bipolar disorders include disruptive life changes and social and environmental stressors. The different factors create feedback loops that can lead to a bipolar disorder or make the patient more likely to relapse.

Mood stabilizers are one treatment that targets neurological factors; when manic, patients may receive an antipsychotic medication or a benzodiazepine.

Treatment that targets psychological factors—particularly CBT—helps patients recognize warning signs of mood episodes, develop better sleeping strategies, and, when appropriate, stay on medication.

Treatments that target social factors include interpersonal and social rhythm therapy (IPSRT), which can increase the regularity of daily events and decrease social stressors; family therapy and education; and group therapy or a self-help group, which is intended to decrease shame and isolation.

Thinking like a clinician

You get in touch with a friend from high school who tells you that she recently had a hypomanic episode. What are two possible DSM-IV-TR diagnoses that she might have had (be specific)? What will determine which di-

- *Thinking Like a Clinician* questions. These questions ask students to apply what they have learned to other people and situations. These questions allow students to test their knowledge of the chapter's material; they may be assigned as homework or used to foster small-group or class discussion.

Thinking like a clinician

Suppose you are a mental health clinician working in a hospital emergency room in the summer; a woman is brought in for you to evaluate. She's wearing a winter coat, and in the waiting room, she talks—or shouts—to herself or an imaginary person. You think that she may be suffering from schizophrenia. What information would you need in order to make that diagnosis? What other psychological disorders could, with only brief observation, appear similar to schizophrenia?

- *Key Terms*. The final element of *Summing Up* is a list of the key terms used in that chapter—the terms that are presented in boldface in the text and are defined in the marginal glossary—with the pages on which the definitions can be found.
- At the very end of *Summing Up*, students are directed to the book-specific website, www.worthpublishers.com/rosenberg, for more study aids and resources pertinent to the chapter.

Integrated Gender and Cultural Coverage

The textbook has extensive culture and gender coverage integrated throughout the entire textbook. The list of coverage and corresponding page numbers are too numerous to list here, but you can find this coverage—in two different indexes—one for Culture and one for Gender—on Worth's free book companion site, which can be reached by going to www.worthpublishers.com/rosenberg. These indexes will help you locate the many different places where we offer this coverage in order to better facilitate learning in your classroom.

Media and Supplements

Online Video Tool Kit for Abnormal Psychology

The Online Video Tool Kit for Abnormal Psychology spans the full range of standard topics for a course in abnormal psychology, combining both research and news footage from the BBC Motion Gallery and CBS News, as well as other great sources. With its superb collection of brief (1 to 5 minutes) clips and emphasis on the neuropsychosocial bases of behavior, the Online Video Tool Kit for Abnormal Psychology gives students a fresh new way to experience the realities of living with psychological disorders from a patient's and a clinician's perspective.

Within the Online Video Tool Kit for Abnormal Psychology, Worth Publishers brings together some of the most famous and important psychology research and news footage ever filmed—and matches it with specific areas of coverage in this textbook. No other abnormal psychology video product available for student purchase offers such a high-quality collection of clips.

Instructors can create assignments and customize their students' experience by annotating the descriptions that accompany each video clip. Or instructors can choose to assign the Online Video Tool Kit for Abnormal Psychology to their students without customizing any of the material. Video clips are keyed to the textbook and

are accompanied by multiple-choice questions so that students can assess their understanding of what they've seen. Student responses are submitted to an online gradebook, making the Online Video Tool Kit for Abnormal Psychology a seamless part of the abnormal psychology course.

Also Available for Instructors: The Video Tool Kit for Abnormal Psychology on CD and close-captioned DVD

The CD and DVD includes the same video clips as the online version. Instructors can play clips to introduce key topics, to illustrate and reinforce specific core concepts, or to stimulate small-group or full classroom discussions. Clips may also be used to challenge students' critical thinking skills—either in class or via independent, out-of-class assignments.

Free Book Companion Site at www.worthpublishers.com/rosenberg

The companion website serves students as a *free*, continuously available online study guide, while providing instructors with a variety of presentation, assessment, and course management resources. Among its many features are Web quizzes by J. D. Rodgers, Hawkeye Community College, and Kanoa Meriwether, University of Hawaii–West Oahu.

CourseSmart eBook at www.coursesmart.com

CourseSmart is a new way for instructors and students to access textbooks online anytime and from anywhere. With thousands of titles related to hundreds of courses, CourseSmart helps instructors choose the best textbook for their class and give their students the option of buying the assigned textbook as a lower cost eTextbook.

Instructor's Resource Manual, by Meera Rastogi, University of Cincinnati (1-4292-3472-5)

The resource manual offers chapter-by-chapter support for instructors using the text, as well as tips for communicating the neuropsychosocial approach to abnormal psychology to students. For each chapter, the manual offers the following:

- A brief outline
- Learning objectives
- List of key terms
- A chapter guide, including an extended chapter outline, point-of-use references to art in the text, and listings of class discussions/activities, assignments, and extra credit projects for each section

The manual recommends additional media for enhancing lectures and assignments, including films, books, magazine and journal articles, and web sites.

Test Bank, by Joy Crawford, University of Washington, and Judith Levine, Farmingdale State College (Printed: 1-4292-3468-7; CD [Mac and Windows on one disc], 1-4292-3473-3)

The test bank offers over 1700 questions, including multiple-choice, true/false, fill-in, and essay questions. The CD version makes it easy for instructors to add, edit, and change the order of questions.

Student Study Guide, by Joe Etherton, Texas State University (1-4292-3470-9)

This helpful student resource offers chapter-by-chapter help for studying and exam preparation.

Acknowledgments

We want to thank the following people, who generously gave of their time to review one or more—in some cases all—of the chapters in this book. Their feedback has helped make this a better book.

We would also like to thank the thoughtful group of instructors who generously attended our 2009 APA focus group in Toronto and who also offered many excellent suggestions, some of which—even in the book's eleventh hour—found their way into the book. They are:

Gina M. Brelsford, Penn State University, Harrisburg
 NiCole T. Buchanan, Michigan State University
 Farah Ibrahim, University of Colorado Denver
 Marva Lewis, Tulane University
 John McIlvried, University of Indianapolis
 Ilyse O'Desky, Kean University
 Crystal Park, University of Connecticut, Storrs
 Jeanne M. Slattery, Clarion University

Although our names are on the title page, this book has been a group effort. Special thanks to a handful of people who did armfuls of work in the early stages of the book's life: Nancy Snidman, Children's Hospital Boston, for help with the chapter on developmental disorders; Shelley Greenfield, McLean Hospital, for advice about the etiology and treatment of substance abuse; Adam Kissel, for help in preparing the first draft of some of the manuscript; Lisa McLellan, senior development editor, for conceiving the idea of "Facts at a Glance" tables; Susan Clancy for help in gathering relevant literature; and Lori Gara-Matthews and Anne Perry for sharing a typical workday of a pediatrician and a school psychologist, respectively.

To the people at Worth Publishers who have helped us bring this book from conception through gestation and birth, many thanks for your wise counsel, creativity, and patience. Specifically, thanks to: Erik Gilg, our acquisitions editor, for his continual assistance and good humor; Jim Strandberg, a freelancer, our final development editor who kept us on track and focused on the end goal and made us

laugh along the way; Michael Kimball, our development editor for most of the first and second drafts and from whom we learned so much about writing; Catherine Woods, senior publisher, for having faith in our vision for this book, providing support at every step along the way, and for putting us in Erik's capable hands; Jane Hoover of Lifland et al., Bookmakers, copyeditor extraordinaire, for reading every word so carefully and catching errors and ambiguities; Babs Reingold, art director, for creating our wonderful design; Jaclyn Castaldo, assistant editor, for her good humor and diligence in handling the endless pages of manuscript and helping us with the reviews; Jenna Gray, project editor at PrePress, Dana Kasowitz, project editor at Worth, and Tracey Kuehn, associate managing editor at Worth, for keeping the final phases of the book on track; Patricia Cateura, photo researcher, and Christine Buese, photo editor, for helping us add photographs to the pages; Diane Kraut, permissions freelancer, for the thankless task of tracking down and obtaining permissions to use quotes, tables, and figures; Nancy Brooks, freelance editor, for carefully matching our words to photos and figures; to the team at Worth who help us introduce ourselves and our book to psychologists who teach abnormal psychology classes: Carlise Stembridge, associate marketing director; Kate Nurre, Executive Marketing Manager; and, Tom Kling, Worth's National Psychology Consultant. We also thank our fantastic supplements team: Sharon Prevost, media and supplements editor, for recruiting a talented team of academic authors and helping them bring the supplements to life: Joe Etherton, Texas State University and Judy Levine, Farmingdale State College (we give both of them an extra special shout out of thanks); Meera Rastogi, University of Cincinnati; Joy Crawford, University of Washington; J. D. Rodgers, Hawkeye Community College; Kanoa Meriwether, University of Hawaii–West Oahu; and the media team of Ramón Rivera Moret, video researcher and producer, Andrea Musick, Senior Media and Supplements Editor, and Alex Levering, freelance editor.

On the personal side, we'd like to thank our children—Neil, David, and Justin—for their unflagging love and support during this project and for their patience with our foibles and passions. We also want to thank: our mothers—Bunny and Rhoda—for allowing us to know what it means to grow up with supportive and loving parents; Steven Rosenberg, for numerous chapter story suggestions; Merrill Mead-Fox, Melissa Robbins, Jeanne Serafin, Amy Mayer, Kim Rawlins, and Susan Pollak, for sharing their clinical and personal wisdom over the last two and a half decades; Michael Friedman and Steven Hyman, for answering our esoteric pharmacology questions; and Jennifer Shephard and Bill Thompson, who helped track down facts and findings related to the neurological side of the project.

ABNORMAL

PSYCHOLOGY

ROBIN S. ROSENBERG AND STEPHEN M. KOSSLYN

Worth Publishers

The History of Abnormal Psychology

Big Edie” (Edith Bouvier Beale, 1894–1977) and her daughter, “Little Edie” (Edith Beale, 1917–2002), lived together as adults for 29 years. Their home was a 28-room mansion, called Grey Gardens, in the chic town of East Hampton, New York. But the Beales were not rich society women, entertaining in grand style. They had few visitors, other than people who delivered food to them daily, and they lived in impoverished circumstances. For the most part, they inhabited only two of the second-floor rooms and an upstairs porch. The house, a wood-shingled seaside home, was falling apart, the paint on the shingles long since having been worn away by the elements. These intelligent women were not simply poor recluses, though. They were unconventional, eccentric women who flaunted the rules of their time and social class.

Let’s consider Big Edie first. In her later years, Big Edie had difficulty walking, and her bedroom was the hub of the Beale women’s lives. It contained a small refrigerator, a hot plate, and up to 52 cats. The room had two twin beds, one for Little Edie to use when in the room, the other for Big Edie. Big Edie made her bed into an unusual nest of blankets (no sheets), and the mattress was so soiled that the grime and the cat droppings were indistinguishable. Cats constantly walked across the bed or rested on it (or on Big Edie), but there was no litter box for them. Consider this exchange between mother and daughter:

Big Edie: This cat’s going to the bathroom right in back of my portrait. [A painting of Big Edie is resting on the floor, against the wall.]

Little Edie: Oh; isn’t that awful?

Big Edie: No. I’m glad he is. I’m glad somebody’s doing something they want to do.

(Maysles & Maysles, 1976)

The room was mopped once a week (Wright, 2007).

Amid the squalor, food was heated or cooked on a hot plate next to Big Edie’s bed. Big Edie hadn’t left the house in decades (except for one occasion; Sheehy, 1972) and would let Little Edie out of her sight for only a few minutes before yelling for her to return to the bedroom. When Big Edie fell off a chair and broke her leg at the age of 80, she refused to leave the house to see a doctor, and refused to allow a doctor to come to the house to examine her leg. As a result, she developed bedsores that became infected and she died at Grey Gardens 7 months later (Wright, 2007).

Chapter Outline

The Three Criteria for Determining Psychological Disorders

- Distress
- Impairment in Daily Life
- Risk of Harm
- Context and Culture

Views of Psychological Disorders Before Science

- Ancient Views of Psychopathology
- Forces of Evil in the Middle Ages and the Renaissance
- Rationality and Reason in the 18th and 19th Centuries

The Transition to Scientific Accounts of Psychological Disorders

- Freud and the Importance of Unconscious Forces
- The Humanist Response
- Lasting Contributions of Psychodynamic and Humanist Approaches

Scientific Accounts of Psychological Disorders

- Behaviorism
- The Cognitive Contribution
- Social Forces
- Biological Explanations
- The Modern Synthesis of Explanations of Psychopathology

Abnormal psychology

The subfield of psychology that addresses the causes and progression of psychological disorders; also referred to as *psychopathology*.

Psychological disorder

A pattern of thoughts, feelings, or behaviors that causes significant personal *distress*, significant *impairment* in daily life, and/or significant *risk of harm*, any of which is unusual for the context and culture in which it arises.

Little Edie was also unusual, most obviously in her style of dress. Little Edie always covered her head, usually with a sweater that she kept in place with a piece of jewelry. She professed not to like women in skirts, but invariably wore skirts herself, typically wearing them upside down so that the waistband was around her knees or calves and the skirt hem bunched around her waist. She advocated wearing stockings *over* pants, and she suggested that women “take off the skirt, and use it as a cape” (Maysles & Maysles, 1976).

Big Edie and Little Edie had limited financial means, but this wasn’t the only reason for their plight. As Little Edie said, “We didn’t live conventionally” (Graham, 1976). Although they were odd, could their behavior be chalked up to eccentricity, or did one or both of them have a psychological disorder? It depends on how “psychological disorder” is defined.

The sort of psychologist who would evaluate Big Edie and Little Edie would specialize in **abnormal psychology** (or *psychopathology*), the subfield of psychology that addresses the causes and progression of psychological disorders (also referred to as *psychiatric disorders*, *mental disorders*, or *mental illness*). How would a mental health clinician—a mental health professional who evaluates or treats people with psychological disorders—determine whether Big Edie or Little Edie (or both of them) had a psychological disorder? The clinician would need to evaluate whether the women’s behavior and experience met three general criteria for psychological disorders.

The Three Criteria for Determining Psychological Disorders

Big Edie and Little Edie came to public attention in 1971 when their unusual living situation was described in the national press. Health Department inspectors had raided their house and found the structure to be in violation of virtually every regulation. “In the dining room, they found a 5-foot mountain of empty cans; in the upstairs bedrooms, they saw human waste. The story became a national scandal. Health Department officials said they would evict the women unless the house was cleaned” (Martin, 2002). The Beales were able to remain in their house after Big Edie’s niece (Jacqueline Kennedy Onassis, the former first lady) paid to have the dwelling brought up to the Health Department’s standards. Several years after this incident, Little Edie is reported to have said, “Do you know, they can get you in East Hampton for wearing red shoes on a Thursday?” (Maysles & Maysles, 1976), attributing the threatened eviction not to the state of their living environment, but to the color of the shoes she wore on a particular day.

In 1976, the Beales were again brought before the public eye with the release of the documentary film *Grey Gardens*, of which they were the “stars.” During the filming, there were so many fleas in the house that the filmmakers strapped flea collars on their ankles before entering (Martin, 2002). At the time of the filming, Big Edie was 79 and her daughter 57, and the film captures their unusual lifestyle.

To determine whether Big Edie or Little Edie had a psychological disorder we must first define a **psychological disorder**: A pattern of thoughts, feelings, or behaviors that causes significant personal *distress*, significant *impairment* in daily life, and/or significant *risk of harm*, any of which is unusual for the context and culture in which it arises (American Psychiatric Association, 2000). Notice the word “significant” in the definition, which indicates that the diagnosis of psychological disorder is applied only when the symptoms have a substantial effect on a person’s life. As we shall see shortly,

Archive Photos/Getty Images

Big Edie and Little Edie Beale were clearly unconventional and eccentric. But did either of them have a psychological disorder? Psychological disorders involve significant distress, impairment in daily life, and/or risk of harm.

all three elements (distress, impairment, and risk of harm) do not need to be present; if two (or even one) of the elements are present to a severe enough degree, then the person's condition may merit the diagnosis of a psychological disorder (see Figure 1.1). Let's consider these three elements in more detail.

Distress

Distress can be defined as anguish or suffering and all of us experience distress at different times in our lives. However, when a person with a psychological disorder experiences distress, it is often *out of proportion* to a situation. The state of being distressed, in and of itself, is not abnormal—it is the degree of distress or the circumstances in which the distress arises that mark a psychological disorder. Some people with psychological disorders exhibit their distress: They may cry in front of others, share their anxieties, or vent their anger on those around them. But other people with psychological disorders contain their distress, leaving family and friends unaware of their emotional suffering. For example, a person may worry excessively but not talk about the worries, or a depressed person may cry only when alone, putting on a mask to convince others that everything is all right.

Please note that severe distress, by itself, doesn't necessarily indicate a psychological disorder. The converse is also true: The absence of distress doesn't necessarily indicate the absence of a psychological disorder. A person can have a psychological disorder without experiencing distress, although it is uncommon. For instance, someone who chronically abuses stimulant medication, such as amphetamines, may not feel distress about misusing the drug but that person nonetheless has a psychological disorder (specifically, a type of *substance use disorder*).

Did either Big Edie or Little Edie exhibit distress? People who knew them describe the Beale women as free spirits, making the best of life. Like many people, they were distressed about their financial circumstances; but, of course, they had real financial difficulties, so these worries were not unfounded. Little Edie did show significant distress in other ways, though. She was angry and resentful about having to be a full-time caretaker for her mother, and the film *Grey Gardens* clearly portrays this: When Big Edie yells for Little Edie to return to her side, Little Edie says in front of the camera, "I've been a subterranean prisoner here for 20 years" (Maysles & Maysles, 1976).

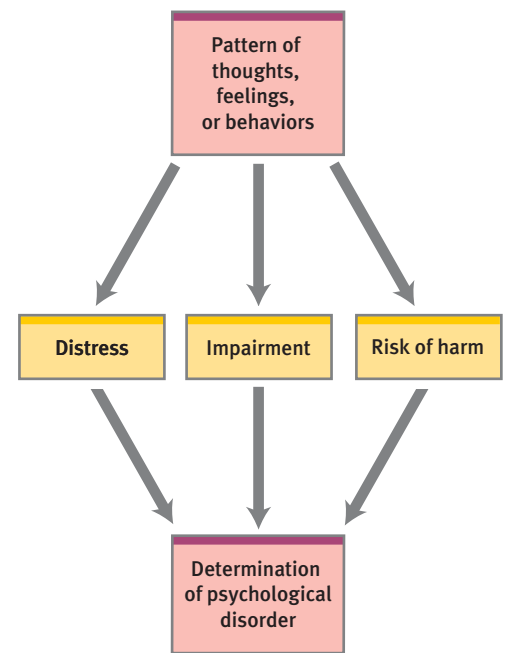

Although Little Edie appears to be significantly distressed, her distress is reasonable *given the situation*. Being the full-time caretaker to an eccentric and demanding mother for decades would undoubtedly distress most people. Because her distress makes sense in its context, it is not an element of a psychological disorder. Big Edie, in contrast, appears to become significantly distressed when she is alone for more than a few minutes, and this response is unusual for the context. We can consider Big Edie's distress as meeting this criterion for a psychological disorder.

Impairment in Daily Life

Impairment is a significant reduction of an individual's ability to function in some area of life. A person with a psychological disorder may be impaired in functioning at school, at work, or in relationships. For example, a woman's drinking problem—and the morning hangovers—may interfere with her ability to do her job. Similarly, a middle-aged man who constantly—20 times a day or more—pesters his wife about whether he has adequately combed his remaining hair over his bald spot may find that his behavior has created considerable marital problems.

But where do mental health clinicians draw the line between normal functioning and impaired functioning? It is the *degree* of impairment that indicates a psychological disorder. When feeling "down" or nervous, we are all likely to function less well—for example, we may feel irritable or have difficulty concentrating.

Figure 1.1

1.1 ► Determining a Psychological Disorder: Three Criteria

The severity of an individual's distress, impairment in daily life, and/or risk of harm determine whether he or she is said to have a psychological disorder. All three elements don't need to be present at a significant level: When one or two elements are present to a significant degree, this may indicate a psychological disorder, provided that the person's behavior and experience are not normal for the context and culture in which they arise.

Researchers have attempted to measure the effects of impairment associated with psychological disorders on the ability to function at work: For every 100 workers, an average of 37 work days per month are lost because of reduced productivity or absences due to psychological disorders (Kessler & Frank, 1997).

Alex Maloney/zefa/Corbis

With a psychological disorder, though, the degree of impairment is atypical for the context—the person is impaired to a greater degree than most people in a similar situation. For instance, after a relationship breakup, most people go through a difficult week or two, though they still go to school or to work. They may not accomplish much, but they soon begin to bounce back. Some people, however, are more impaired after a breakup—they may not make it out of the house or even out of bed; they may not bounce back after a few weeks. These people are significantly impaired.

One type of impairment directly reflects a particular pattern of thoughts: a **psychosis** is an impaired ability to perceive reality to the extent that normal functioning is not possible. There are two forms of psychotic symptoms: hallucinations and delusions. **Hallucinations** are sensations that are so vivid that the perceived objects or events seem real, although they are not. Hallucinations can occur

in any of the five senses, but the most common type is auditory hallucinations, in particular, hearing voices. However, a hallucination—in and of itself—does not indicate psychosis or a psychological disorder. Rather, this form of psychotic symptom must arise in a context that renders it unusual and indicates impaired functioning.

The other psychotic symptom is **delusions**—persistent false beliefs that are held despite evidence that the beliefs are incorrect or exaggerate reality. The content of delusions can vary across psychological disorders. Common themes include an individual's belief that:

- other people—the FBI, aliens, the neighbor across the street—are after the individual (*paranoid or persecutory delusions*);
- his or her intimate partner is dating or interested in another person (*delusional jealousy*);
- he or she is more powerful, knowledgeable, or influential than is true in reality and/or that he or she is a different person, such as the president or Jesus (*delusions of grandeur*);
- his or her body—or a part of it—is defective or functioning abnormally (*somatic delusion*).

Were the Beale women impaired? The fact that they lived in such squalor implies an inability to function normally in daily life. They knew about hygienic standards but didn't live up to them. Whether the Beales were impaired is complicated, however, by the fact that they viewed themselves as bohemians, set their own standards, and did not want to conform to mainstream values (Sheehy, personal communication, December 29, 2006). Their withdrawal from the world can be seen as clear evidence that they were impaired, though. Perhaps they couldn't function in the world, and so retreated to Grey Gardens.

The women also appear to have been somewhat paranoid: In the heat of summer, they left the windows nailed shut (even on the second floor) for fear of possible intruders. And Little Edie seems to have bizarre beliefs—for example, that wearing red shoes on a Thursday led to the threatened eviction—which may suggest that she had problems in understanding cause-and-effect in social interactions. The women's social functioning was impaired to the extent that their paranoid beliefs led to strange behaviors that isolated them. In addition, their beliefs led them to behave in ways that made the house so uncomfortable—extreme temperatures and fleas—that relatives wouldn't visit. And Big Edie's distress at being alone for even a few minutes indicates that her ability to function independently was impaired. It seems, then, that a case could be made that both of them—Big Edie more so than Little Edie—were impaired and unable to function normally.

Psychosis

An impaired ability to perceive reality to the extent that normal functioning is not possible. The two types of psychotic symptoms are hallucinations and delusions.

Hallucinations

Sensations that are so vivid that the perceived objects or events seem real, although they are not. Hallucinations can occur in any of the five senses.

Delusions

Persistent false beliefs that are held despite evidence that the beliefs are incorrect or exaggerate reality.

Risk of Harm

Some people take more risks than others. They may drive too fast or drink too much. They may diet too strenuously, exercise to an extreme, gamble away too much money, or have unprotected sex with multiple partners. For such behavior to indicate a psychological disorder, it must be outside the normal range. The criterion of danger, then, refers to symptoms of a psychological disorder that lead to life or property being put at risk, either accidentally or intentionally. For example, a person with a psychological disorder may be in danger when:

- depression and hopelessness lead him or her to attempt suicide;
- auditory hallucinations interfere with normal safety precautions, such as checking for cars before crossing the street;
- body image and other psychological disturbances lead the person to refuse to eat enough food to maintain a healthy weight, which in turn leads to malnutrition and medical problems.

Psychological disorders can also lead individuals to put other people's lives at risk. Examples of this type of danger include:

- auditory hallucinations that command the individual to harm another person;
- suicide attempts that put the lives of other people at risk, such as driving a car into oncoming traffic;
- paranoia so extreme that a parent kills his or her children in order to "save" them from a greater evil.

The house in which Little Edie and Big Edie lived had clearly become dangerous. Wild animals—raccoons and rats—roamed the house, and the ceiling was falling down. But having too little money to make home repairs doesn't mean that someone has a psychological disorder. Some might argue that perhaps the Beale women simply weren't aware of the danger. They were, however, aware of *some* dangers: When their heat stopped working, they called a heating company to repair it, and ditto for the electricity. They had a handyman come in regularly to repair fallen ceilings and walls and to fill holes that rats might use to enter (Wright, 2007). It's hard to say, however, whether they realized the extent to which their house itself had become dangerous.

On at least one occasion in her early 30s, Little Edie appears to have been a danger to herself. Her cousin John told someone about "a summer afternoon when he watched Little Edie climb a catalpa tree outside Grey Gardens. She took out a lighter. He begged her not to do it. She set her hair ablaze" (Sheehy, 2006). From then on, her head was at least partially bald, explaining her ever-present head covering.

Aside from Little Edie's single episode with the lighter, it's not clear how much the Beale women's behavior led to a significant risk of harm. Big Edie recognized most imminent dangers and took steps to ensure her and her daughter's safety. The women were not overtly suicidal nor were they interested in harming others. The only aspect of their lives that suggests a risk of harm was the poor hygienic standards they maintained.

Context and Culture

As we noted earlier, what counts as a significant level of distress, impairment, or risk of harm depends on the context in which it arises. That human waste was found in an empty room at Grey Gardens might indicate abnormal behavior, but the fact that the plumbing was out of order for a period of time might provide a reasonable explanation. Of course, knowing that the human waste was allowed to remain in

Using this book's definition of a psychological disorder, did either of the Beales have a disorder? Big Edie exhibited *distress* that was inappropriate to her situation; both women appeared to have an *impaired* ability to function. The *risk of harm* to the women, however, is less clear-cut.

Everett Collection

**Table 1.1 ► Psychological Disorders:
Facts at a Glance**

- Psychological disorders are a leading cause of disability and death, ranked second, after heart disease (Murray & Lopez, 1996).
- About half of all Americans will likely develop at least one of 30 common psychological disorders, such as depression, anxiety, or substance abuse, over the course of their lives; in half of the cases, symptoms will begin by age 14 (Kessler, Berglund, et al., 2005).
- Those born more recently have a higher likelihood of developing a psychological disorder than those born earlier (Kessler, Berglund, et al., 2005).
- Within a given year, about 25% of Americans experience a diagnosable or diagnosed mental disorder; of these cases, almost a quarter are severe (Kessler, Chiu, et al., 2005).
- Disadvantaged ethnic groups—Hispanics and Blacks—do not have a higher risk for psychological disorders overall (Breslau et al., 2005).

place after the plumbing was fixed would probably decide the question of whether the behavior was abnormal.

In addition, the Beales appeared to have delusions—that people wanted to break into the house or kidnap them, and that then-President Nixon might have been responsible for the 1971 “raid” on their house by the town health inspectors (Wright, 2007). But these delusions aren’t necessarily as farfetched as they might sound. Their house *was* broken into in 1968, and, as relatives of Jackie Kennedy, they had cars with Secret Service agents posted outside their house while John F. Kennedy was president.

Behavior that seems inappropriate in one context may make sense from another point of view. Having a psychological disorder isn’t merely being different—we wouldn’t say that someone was abnormal simply because he or she was avant-garde or eccentric or acted on unusual social, sexual, political, religious, or other beliefs. And as we’ve seen with the Beales, the effects of context can blur the line between being different and having a disorder. Table 1.1 provides additional information about psychological disorders.

Culture, too, can play a crucial role in how mental illness is diagnosed. To psychologists, **culture** is the shared norms and values of a society; these norms and values are explicitly and implicitly conveyed to members of the society by example and through the use of reward and punishment. Different societies and countries have their own cultures, each with its own view of what constitutes mental health and mental illness, and even what constitutes distress. For example, in some cultures, distress may be conveyed by complaints of fatigue or tiredness rather than by sadness or depressed mood. Some sets of symptoms that are recognized as disorders in other parts of the world are not familiar to most Westerners. One example, described in Case 1.1, is *koro*, a disorder that arises in some people from countries in southeast Asia. Someone with *koro* rapidly develops an intense fear that his penis—or her nipples and vulva—will retract into the body and cause death (American Psychiatric Association, 2000). This disorder may break out in clusters of people, like an epidemic (Bartholomew, 1998; Sachdev, 1985). Similar genital-shrinking fears have been reported in India and in West African countries (Dzokoto & Adams, 2005; Mather, 2005).

CASE 1.1 ► FROM THE OUTSIDE: Cultural Influence on Symptoms

Although most cases of *koro* appear to resolve quickly, in a minority of cases, symptoms may persist.

A 41-year-old unmarried, unemployed male from a business family, presented with the complaints of gradual retraction of penis and scrotum into the abdomen. He had frequent panic attacks, feeling that the end had come. The symptoms had persisted more than 15 years with a waxing and waning course. During exacerbations he spent most of his time measuring the penis by a scale and pulling it in order to bring it out of [his] abdomen. He tied a string around it and attached it to a hook above to prevent its shrinkage during [the] night. . . . He did not have regular work and was mostly dependent on the family.

(Kar, 2005, p. 34)

Culture

The shared norms and values of a society that are explicitly and implicitly conveyed to its members by example and through the use of reward and punishment.

Another example of a set of symptoms not familiar in Western cultures is *possession trance*, which occurs when spirits (perhaps of a loved one who has died or an ancestor) purportedly take over an individual’s body (often a woman’s) and cause it to participate in a ritual. Possession trance occurs in many cultures and, in context, does not indicate psychosis; it can be a way for people who traditionally have less power to speak their minds in a culturally sanctioned way (Bourguignon, 2004).

Constellations of symptoms, such as *koro* and possession trance, that are generally observed only in certain countries or cultures are said to be *culture-bound*.

Even within a country or culture, there are different segments—*subcultures*—that have their own norms and values, and these subcultures may support divergent views about mental health and mental illness. For instance, families who immigrated to the United States from Southeast Asia tend to value self-control and are more likely to interpret a child's pattern of physically active or aggressive behavior as a problem than are most Americans, who view such behavior in children as normal and healthy.

In addition, culture can shape the form taken by psychological distress and any ensuing problematic behaviors. As we shall see in the rest of this chapter, culture—and its evolution over time—affects the way individuals with mental illness see themselves and how other people respond to them. However, cultural norms about psychopathology are not set in stone but can shift. Consider that, in 1851, Dr. Samuel Cartwright of Louisiana wrote an essay in which he declared that slaves' running away was evidence of a serious mental disorder, which he called “drapetomania” (Eakin, 2000). More recently, homosexuality was officially considered a psychological disorder in the United States until 1973, when it was removed from the *Diagnostic and Statistical Manual of Mental Disorders*, the manual used by mental health clinicians to classify psychological disorders.

Cultural norms also affect how mental health professionals view mental illness. In fact, in the 1960s and 1970s, some researchers and psychiatrists believed that culture and context were so important that behavior that was merely unusual or undesirable had come to be labeled as mental illness. Thomas Szasz (1960) argued that because all people engage in “us-versus-them” thinking, it is easy for a society to stigmatize people who are noticeably different. That is, culturally undesirable behaviors, emotional difficulties, and coping problems may be inaccurately called mental illness. In fact, Szasz proposed that mental illness is actually a myth.

Although culture is undeniably important, it does not entirely define mental illness. As we shall show in this book, many studies have documented both commonalities across a wide range of culture and the contribution of neurological factors to the development and expression of mental illness. The assertion that mental illness is a myth is therefore not true and has been relegated to history. However, it is always important for mental health professionals to ensure that the diagnosis of mental illness is not used simply to label people who are different or, as in the former Soviet Union, who question the policies of the government or those in authority. Diagnosing someone with a mental illness assigns a label that may influence how the diagnosed person feels about himself or herself and how that person is seen and treated by others (Eriksen & Kress, 2005).

Let's examine the behavior of the Beales within their context and culture. Big Edie's father claimed that his ancestors were prominent French Catholics; she and her siblings grew up financially well off. She was a singer and a performer, but, as a product of her time, she was expected to marry well (McKenna, 2004). Her father arranged for her to wed New York lawyer Phelan Beale, from a socially prominent Southern family (Rakoff, 2002). Little Edie was born about a year later, followed by two brothers. Big Edie was very close to her daughter, even keeping her out of school when Little Edie was 11 and 12, ostensibly for “health reasons.” However, Little Edie was well enough to go to the movies with her mother every day and on a shopping trip to Paris (Sheehy, 2006).

Charles & Josette Lenars/Corbis

Although you may view the intentional facial scarring of this man from a tribe in West Africa as unusual, you probably do not view it as an indicator of a psychological disorder. But what if your neighbor or classmate had similar scarring—might you view it as a sign of a psychological disorder? Notice that the context of the behavior and the culture of the person influence your assessment.

After she was married, Big Edie continued to sing, to write songs with her accompanist, and even to record some of those songs. At that time, however, cultural conventions required a woman of Big Edie's social standing to stop performing after marrying, even if such performances generally were limited to social functions. Big Edie's need to perform was almost a compulsion, though, and she would head straight to the piano at family gatherings. Her nieces and nephews were eager to hear her sing, but the adults in her extended family, and her own children, were not. Her parents and siblings barely tolerated her at family gatherings (Davis, 1969). Clearly, even as a young woman, Big Edie was already behaving in ways that were at odds with cultural norms.

In 1934, when Little Edie was 16, Big Edie and her husband divorced; at that time, divorce was much less common and much less socially acceptable than it is today. This event marked the start of Big Edie's life as a recluse (Davis, 1969). By 1936, the house and grounds began to suffer from neglect (Davis, 1996). In 1942, Big Edie's husband stopped supporting her financially after she showed up late for their son's wedding, dressed inappropriately—another time when Big Edie's behavior was unusual for the context and culture. Big Edie's father was also angry with her for her inappropriate behavior, but he didn't want her to starve. He set up a trust fund for her, which provided a small monthly allowance, barely enough to pay for food and other necessities.

Like her mother, Little Edie was artistically inclined. She aspired to be an actress, dancer, and poet, and she claimed that wealthy men such as Howard Hughes and Joe Kennedy, Jr. (John F. Kennedy's older brother, who died in World War II) proposed marriage, which she refused. Little Edie's cousin said of her, "She had a very, very fertile imagination" (Martin, 2002). In 1946, she left home to live in New York City and work as a model, but her father disapproved of this as he had disapproved of his wife's musical performances (Sheehy, 2006).

In 1952, after 6 years of being separated from her daughter, Big Edie became seriously depressed (Sheehy, 2006), although there is no information about her specific symptoms. She spent 3 months calling Little Edie daily, begging her to return to Grey Gardens. Eventually, Little Edie moved back to take care of Big Edie. When she did, her artistic aspirations became only dreams and fantasies. The documentary film *Grey Gardens* vividly captures Little Edie's palpable disappointment at the path her life took—becoming a round-the-clock caretaker to her mother, a disappointed woman herself.

So far, we've seen that psychological disorders lead to significant distress, impairment in daily life, and/or risk of harm. We've also seen that the determination of a disorder depends on the culture and context in which these elements occur. A case could be made that the Beale women did have psychological disorders; let's consider each one in turn. Big Edie exhibited significant distress when alone for more than a few minutes; her reclusiveness and general lifestyle suggest an impaired ability to function independently in the world—perhaps to the point where there might be a risk of harm to herself or her daughter. Her behavior and experience appear to satisfy the first two criteria, which is enough to indicate that she had a psychological disorder. Moreover, Big Edie suffered from depression at some point after Little Edie moved to New York, and she experienced enough distress that she begged her daughter to return to Grey Gardens.

As for Little Edie, her distress was appropriate for the context, and thus would not meet the first criterion. Her ability to function independently, though, appears to have been significantly impaired, which also increased the risk of harm to herself and her mother. It appears that she too suffered from a psychological disorder. However, these conclusions must be tentative—they are based solely on films of the women and other people's descriptions and memories of them.

Now that we know what is required to determine whether someone has a psychological disorder, we'll spend the rest of this chapter looking at how psychopathology has been explained through the ages, up to the present.

Key Concepts and Facts About The Three Criteria for Determining Psychological Disorders

- A psychological disorder is a pattern of thoughts, feelings, or behaviors that causes significant distress, impaired functioning in daily life, and/or risk of harm.
- The distress involved in a psychological disorder is usually out of proportion to the situation.
- Impairment in daily life may affect functioning at school, at work, at home, or in relationships. Moreover, people with a disorder are impaired to a greater degree than most people in a similar situation. A psychosis is a relatively easily identifiable type of impairment that includes hallucinations or delusions.
- A psychological disorder may lead to behaviors that create a significant risk of harm to the person or to others.
- Mental health clinicians and researchers recognize that context and culture in part determine whether a person's state involves significant distress, impairment, or risk of harm. In particular, people from different cultures may express distress differently, and some sets of symptoms, such as possession trance, may, in fact, not be a disorder in certain cultures.

Views of Psychological Disorders Before Science

Psychological disorders have probably been around as long as there have been humans. In every age, people have tried to answer the fundamental questions of why mental illness occurs and how to treat it. In this section, we begin at the beginning, by considering the earliest known explanations of psychological disorders.

Ancient Views of Psychopathology

Symptoms of psychopathology can take a toll both on the people suffering from a disorder and on others affected by their symptoms. Throughout history, humans have tried to understand the causes of mental illness in an effort to counter its detrimental effects. The earliest accounts of abnormal thoughts, feelings, and behaviors focused on two possible causes: (1) supernatural forces and (2) an imbalance of substances within the body.

Supernatural Forces

Societies dating as far back as the Stone Age appear to have explained psychological disorders in terms of supernatural forces (Porter, 2002)—magical or spiritual in nature. Both healers and common folk believed that the mentally ill were possessed by spirits or demons, and possession was often seen as punishment for some religious, moral, or other transgression.

In the ancient societies that understood psychological disorders in this way, treatment often consisted of *exorcism*—a ritual or ceremony intended to force the demons to leave the individual's body and restore the person to a normal state. The healer led the exorcism, which in some cultures consisted of reciting incantations, speaking with the spirit, and inflicting physical pain to induce the spirit to leave the individual's body (Goodwin, Hill, & Attias, 1990). This belief in supernatural forces was common in ancient Egypt and Mesopotamia (and, as we shall see shortly, arose again in the Middle Ages in Europe and persists today in some cultures). Although it is tempting to regard such a view of psychopathology—and its treatment—as barbaric or uncivilized, the healers were simply doing the best they could in trying to understand and treat devastating impairments.

Chinese Qi

Healers in China in the 7th century B.C.E. viewed psychological disorders as a form of physical illness, reflecting imbalances in the body and spirit. This view, which continues to be common in China to this day, rests on the belief that all living things

Archaeologists have found evidence of *trephination*, the boring of a hole in the skull, dating as far back as 7,000 years ago. In some ancient cultures, insanity was thought to arise from supernatural forces; one explanation for trephination is that the hole allowed these supernatural forces to escape. Treatment for mental illness is usually related to the prevailing explanation of the cause of the mental illness.

have a life force, called *qi* (pronounced “chee” as in *cheetah*), which flows through the body along 12 channels to the organs. Illness results when *qi* is blocked or seriously imbalanced. This is one of the oldest biological explanations of psychological disorders. Even today, Chinese treatment for various problems, including some psychological disorders, aims to restore the proper balance of *qi*. Practitioners use a number of techniques, including acupuncture and herbal medicine.

Ancient Greeks and Romans

Like the ancient Chinese, the ancient Greeks viewed mental illness as a form of bodily illness (U.S. National Library of Medicine, 2005). According to their theory, mental illness arose through an imbalance of four *humors* (that is, bodily fluids): black bile, blood, yellow bile and phlegm. Each humor corresponded to one of four basic elements: earth, air, fire, water. The ancient Greeks believed that differences in character reflected the relative balance of these humors, and an extreme imbalance of the humors resulted in illness—including mental illness (see Table 1.2). Most prominent among the resulting mental disorders were *mania* (marked by excess uncontrollability, arising from too much of the humors blood and yellow bile) and *melancholy* (marked by anguish and dejection, and perhaps hallucinations, arising from too much black bile). The goal of treatment was to restore the balance of humors through diet, medicine, or surgery (such as bleeding, or letting some blood drain out of the body if the person had too much of the humor blood).

Table 1.2 ▶ The Four Humors

Element	Humor	Material and Function	Character
Earth	Black Bile	A dark liquid that causes other fluids and parts of the body to darken (such as stool, hair, skin)	Gloomy or sullen
Air	Blood	A red liquid that promotes vitality	Lively and energetic, but easily angered
Fire	Yellow Bile	A gastric fluid that promotes digestion	Irritable and biting
Water	Phlegm	A lubricant and coolant that is most evident in excess (as in tears or sweat)	Indifferent and apathetic

Beginning with the physician Hippocrates (460–377 B.C.E.), the ancient Greeks emphasized reasoning and rationality in their explanations of natural phenomena, rejecting supernatural explanations. In many ways, Hippocrates was a visionary: He suggested that the brain, rather than any other bodily organ, is responsible for mental activity, and that mental illness arises from abnormalities in the brain (Shaffer & Lazarus, 1952). Today, the term *medical model* is used to refer to Hippocrates’ view that all illness, including mental illness, has its basis in biological disturbance. Nevertheless, regardless of how insightful the Greeks’ basic theory of disorders may have been, their treatments were not sophisticated by today’s standards. Such treatments included music, bathing, diets, and bleeding.

Galen (131–201 C.E.), a Roman doctor, extended the ideas of the Greeks. Galen proposed that imbalances in humors produced emotional imbalances—and such emotional problems in turn could lead to psychological disorders. His view of the importance of emotions extended to treatment: Just as the humors must be balanced for physical health, so too must the emotions (U.S. National Library of Medicine, 2005). However, the fall of the Roman Empire and the spread of Christianity

throughout Europe affected the view of psychopathology: The views that biological or emotional forces contributed to psychopathology waned, as did scientific investigations into its causes.

Forces of Evil in the Middle Ages and the Renaissance

With the rise of Christianity in Europe, psychopathology came to be attributed to forces of evil; this view persisted from the Middle Ages until the early Renaissance.

The Middle Ages

During the Middle Ages (approximately 500–1400 C.E.), the Greek emphasis on reason and science lost influence, and madness was once again thought to result from supernatural forces, now being conceived as a consequence of a battle between good and evil for the possession of an individual's soul. Prophets and visionaries were believed to be possessed or inspired by the will of God. For example, French heroine Joan of Arc reported that she heard the voice of God command her to lead a French army to drive the British out of France. The French hailed her as a visionary. In contrast, other men and women who reported such experiences usually were believed to be possessed by the devil or were viewed as being punished for their sins. Treatment consisted of attempts to end the possession: exorcism, torture (with the idea that physical pain would drive out the evil forces), starvation, and other forms of punishment to the body. Such inhumane treatment was not undertaken everywhere, though. As early as the 10th century, Islamic institutions were caring humanely for those with mental illness (Sarró, 1956).

The Renaissance

During the Renaissance (15th through 17th centuries), mental illness continued to be viewed as a result of demonic possession, and witches (who were possessed by, or in league with, the devil) were held responsible for a wide variety of ills. Indeed, witches were blamed for other people's physical problems and even for societal problems, such as droughts or crop failures. As before, treatment was primarily focused on ridding the individual of demonic forces, in one way or another.

During the Renaissance, people believed that witches put the whole community in jeopardy through their evil acts and through their association with the devil (White, 1948). The era is notable for its witch hunts, which were organized efforts to track down individuals who were believed to be in league with the devil and to have inflicted possession on other people (Kemp, 2000). Once found, these "witches" were often burned alive. The practice of witch burning spread throughout Europe and the American colonies:

Judges were called upon to pass sentence on witches in great numbers. A French judge boasted that he had burned 800 women in 16 years on the bench; 600 were burned during the administration of a bishop in Bamberg. The Inquisition, originally started by the Church of Rome, was carried along by Protestant Churches in Great Britain and Germany. In Protestant Geneva 500 persons were burned in the year 1515. Other countries, where there were Catholic jurists, boasted of as many burnings. In Treves, 7,000 were reported burned during a period of several years.

(Bromberg, 1937, p. 61, quoted in White, 1948, p. 8)

Rationality and Reason in the 18th and 19th Centuries

At the end of the Renaissance, rational thought and reason gained acceptance again. French philosopher René Descartes proposed that mind and body are distinct, and that bodily illness arises from abnormalities in the body, whereas mental illness arises from abnormalities in the mind. Similarly, according to the 17th-century British philosopher John Locke, insanity is caused by irrational thinking, and so could be treated by helping people regain their rational and logical thought process.

Bettmann/Corbis

Joan of Arc (1412–1430) was a young Frenchwoman who led a French army and successfully drove the English out of France. She said that God spoke to her and told her to help her people. The French viewed her as a visionary, but the English believed her to be possessed by the devil.

Asylums

Institutions to house and care for people who are afflicted with mental illness.

Asylums were initially meant to be humane settings for those with mental illness. A victim of their success, asylums became overcrowded as a result of an influx of delinquents and people with certain medical illnesses. With overcrowding, the primary purpose of asylums became incarceration rather than treatment, as was true of the Hospital of St. Mary of Bethlehem (“Bedlem”) in the early 18th century.

Burstein Collection/Corbis

Franz Mesmer believed that hysteria arises from blocked electromagnetic forces. He stated that his technique used the magnetic forces in his own hand to unblock electromagnetic forces in the patient when he moved his hand over—but not touching—her body. In fact, this treatment probably induced either a placebo effect or a hypnotic trance.

Bettmann/Corbis

However, deficits in rationality and reason turned out to be insufficient as an explanation for psychological disorders or as a foundation for treatment. In the Western world, the mentally ill were treated differently from country to country and decade to decade. As we see in the following sections, various approaches were tried in an effort to cope with the mentally ill and with mental illness itself.

Asylums

The Renaissance was a time of widespread innovation and enlightened thinking. For some people, this enlightenment extended to their view of how to treat those with mental illness—humanely. Some groups founded **asylums**, institutions to house and care for individuals who were afflicted with mental illness. Such institutions coped with the mentally ill as people. In general, asylums were founded by religious orders; the first of this type was opened in Valencia, Spain, in 1409 (Sarró, 1956). In subsequent decades, asylums for the mentally ill were built throughout Europe.

Initially, asylums were places of refuge for the mentally ill. But before long, delinquents and others were sent to asylums, and the facilities became overcrowded. Their residents were then more like inmates than patients. At least in some cases, people were sent to asylums simply to keep them off the street, without any effort to treat them.

Perhaps the most famous asylum from this era was the Hospital of St. Mary of Bethlehem in London (commonly referred to as “Bedlem” or later as “Bedlam,” which became a word meaning “confusion and uproar”). In 1547, that institution shifted from being a general hospital to an asylum used to incarcerate the mad, particularly those who were poor. Residents were chained to the walls or floor or put in cages and displayed to a paying public much like animals in a zoo (Sarró, 1956). Officials promoted such displays as educational, allowing the public to observe what was believed to be the excesses of sin and passion. The idea was that such exhibitions would deter people from indulging in behaviors believed to lead to mental illness.

Novel Humane Treatments

At the same time that asylums were incarcerating many of the mentally ill, some people were trying to treat psychological disorders. For example, in Europe during the 18th and 19th centuries, a common psychological disorder, particularly among women, was *hysteria*—a disorder marked by physical symptoms such as paralysis, blindness, and bodily tics for which doctors could find no specific medical cause. Franz Mesmer (1734–1815) caused a stir among the French by proposing a new theory to explain hysteria. His view was that all living things possessed *animal magnetism*—a fluid of electromagnetism that flowed in the body through fine channels—and that hysteria was caused by blocked electromagnetic forces. Treatment, according to Mesmer, should unblock the flow. The technique he used to do so came to be called *mesmerism*. It consisted of the healer’s passing his hands (which contained his own magnetism) very close to the patient’s body to unblock the patient’s flow of electromagnetism; Mesmer called these hand motions “magnetic passes” (Crabtree, 2000).

Although Mesmer’s treatment was sometimes successful, this didn’t necessarily indicate that his theory was correct. For example, the successes might have occurred simply because of a placebo effect (such as occurs when a sugar pill helps patients recover, as we will discuss in Chapter 5), or possibly because the treatment induced a hypnotic trance, which is used even today to

alleviate pain and other medical symptoms. A scientific commission, headed by Benjamin Franklin, investigated mesmerism and discredited the theory of electromagnetism and the treatment based on that theory (Chaves, 2000). Nonetheless, Mesmer's treatment was more humane than many that had come before it.

The humane treatment of people with psychological disorders found a great supporter in French physician Phillipe Pinel (1745–1826). He and others transformed the lives of asylum patients at the Salpêtrière and Bicêtre Hospitals (for women and men, respectively) in Paris: In 1793, Pinel removed their chains and stopped “treatments” that involved bleeding, starvation, and physical punishment (Porter, 2002). Pinel and his colleagues believed that “madness” is a disease; they carefully observed patients and distinguished between different types of “madness.” Pinel also identified *partial insanity*, where the individual was irrational with regard to one topic but was otherwise rational. He believed that such a person could be treated through psychological means, such as reasoning with him or her, which was one of the first *mental* treatments for *mental* disorders.

During the same period in England, King George III (1738–1820) displayed psychotic symptoms during his reign. In 1788, Francis Willis, who ran a private asylum, treated King George by creating blisters on his skin to draw out the “evil humors.” When the king exhibited “mad” behaviors, Willis punished him, for example, by restraining him in a type of straightjacket, in an effort to bring him to his senses (Fraser, 2000). Willis used restraint when he felt it was necessary but also tried to talk people out of their delusions, which is another *mental* treatment for mental disorders. More recently, scientists have proposed that King George probably suffered from *porphyria*, a rare genetic disorder of metabolism that can cause delusions and confusion; in the king's case, it was likely triggered by exposure to arsenic (Cox et al., 2005). When the king recovered from his bout of porphyria, the methods that Willis had used to treat his “madness” were, for a short time, hailed as cures for insanity.

Moral Treatment

During King George III's reign, a group of Quakers in York, England, developed a treatment that was based on their personal and religious belief systems. Mental illness was seen as a temporary state during which the individual was deprived of his or her reason. **Moral treatment** consisted of providing an environment in which people with mental illness were treated with kindness and respect. The “mad” residents lived out in the country, worked, prayed, rested, and functioned as a community. Over 90% of the residents treated this way for a year recovered (Whitaker, 2002), at least temporarily.

Moral treatment also began to be used in the United States. Around the time that Pinel was unchaining the mentally ill in France, Doctor Benjamin Rush (1745–1813), a physician at the Pennsylvania Hospital in Philadelphia, moved the mentally ill from filthy basement cells to rooms above ground level, provided them with mattresses and meals, and treated them with respect.

In Massachusetts and other states, however, the mentally ill were still frequently incarcerated with felons under deplorable conditions. This began to change in the 1840s after Dorothea Dix (1802–1887), a schoolteacher, witnessed the terrible conditions that mental patients were forced to endure in asylums. She was inspired to engage in lifelong humanitarian efforts to ensure that the mentally ill were housed separately from criminals and treated humanely, in both public and private asylums (Viney, 2000). Dix also helped to raise millions of dollars for building new mental health facilities throughout the United States. Her work is all the more remarkable because she undertook it at a time when women did not typically participate in such political endeavors.

Moral treatment proved popular, and its success had an unintended consequence: Unlike private asylums, public asylums couldn't turn away patients, and thus their population increased tenfold as the mentally ill were joined by people with epilepsy and others with neurological disorders, as well as many who might otherwise have gone to jail. As a result, public institutions housing the mentally ill

Dagiti Orti/The Art Archive

King George III of England exhibited signs of psychosis—hallucinations and delusions. Among the treatments the king received were various forms of punishment, which the man in charge of his care, Francis Willis, believed would induce the king to “come to his senses.” The king's madness was probably a result of a medical condition, porphyria, unidentified at that time, and Willis's treatment probably delayed his recovery.

Humanitarian Dorothea Dix worked tirelessly for humane treatment of the mentally ill in the United States (Viney, 2000).

Moral treatment

The treatment of the mentally ill that provided an environment in which people with mental illness were treated with kindness and respect and functioned as part of a community.

again became overcrowded and underfunded, and moral treatment—or treatments of any kind—were no longer provided (Porter, 2002). Sedation and management became the new goals.

Neurasthenia

By the end of the 19th century in Europe and North America, “madness” was generally seen as caused by a medical abnormality. The specific type of medical abnormality varied, however, from country to country and from decade to decade. In the United States, the pace of life increased with the advent of the telegraph and the railroad. More and more men and women were diagnosed with *neurasthenia*—literally, nerve weakness—which was accompanied by the symptoms of low mood and mental and physical fatigue. Treatment, administered by a physician, included rest, sedatives, and induced vomiting or bleeding.

Key Concepts and Facts About Views of Psychological Disorders Before Science

- The oldest known view of psychopathology is that it arose from supernatural forces, either magical or spiritual in nature. Treatment included exorcism. Ancient and modern Chinese views of psychopathology consider its cause to be blocked or significantly imbalanced *qi*. The ancient Greeks attributed mental illness to an imbalance of bodily humors. The term *medical model* refers to Hippocrates’ view that illness (including psychological disorders) is due to a biological disturbance.
- The Middle Ages saw a resurgence of the view that supernatural forces cause psychopathology; prophets and visionaries were believed to be possessed or inspired by the will of God. This view persisted into the Renaissance, when mental illness was viewed as the result of demonic possession, and witches were thought to be possessed by, or in league with, the devil. Treatment of the mentally ill consisted of exorcism; those believed to be witches were burned alive. By the end of the Renaissance, however, the mentally ill began to be treated more humanely, and asylums were built throughout Europe; over time, however, these asylums became a place to keep the mentally ill poor off the street, which led to overcrowded facilities.
- In the years immediately following the Renaissance, mental illnesses were thought to arise from irrational thinking, but this approach did not lead to consistent cures. Mesmer proposed that hysteria was caused by blocked electromagnetic forces in the body, and he developed a humane technique—mesmerism—to unblock the flow. His treatment was sometimes successful, possibly because it induced a hypnotic trance.
- Beginning in the 1790s, Pinel championed humane treatment for those in asylums in France. Based on careful observation, he proposed that there were different types of madness, and he used a mental treatment—reasoning with patients—to treat mental disorders. In other European settings, patients were given moral treatment, which centered on having them live and work within a community in the countryside.
- In the United States, Benjamin Rush initiated the effort to treat the mentally ill more humanely; similarly, Dorothea Dix strove to ensure that the mentally ill were housed separately from criminals and treated humanely. However, public institutions for the mentally ill became overcrowded and underfunded, which reduced the amount and quality of the treatment that was provided. By the end of the 19th century in Europe and North America, “madness” was generally viewed as caused by a medical abnormality. The characterization of the specific type of medical abnormality varied, however, from country to country and from decade to decade.

The Transition to Scientific Accounts of Psychological Disorders

Each of the prescientific explanations of psychological disorders proved inadequate. However, those who cared for and had responsibility for the mentally ill were making their best guesses about the cause of such illness and how best to cope with those who were afflicted. They were trying to help the individuals who experienced incredible distress and inability to function. But because the explanations proved inadequate over the course of time—and the responses to the mentally ill derived from them were not satisfactory—pressure built for more effective and enduring treatments.

There is one positive legacy from the prescientific era: The mentally ill came to be regarded as ill, and so were treated humanely, at least in some places and some eras. If the Beales had lived in the 18th century or earlier, they might have ended up as exhibits in an English asylum. If they had lived at the end of the 19th century, they would probably have been treated much better—although their chances of receiving effective treatment would still have been hit-or-miss. Fortunately, the situation improved dramatically during the 20th century. If the Beales were diagnosed today, they would almost certainly receive treatments that would enable them to function more effectively in the world. Let's now consider the crucial transition from prescientific times to today, the period when investigators worked to develop genuinely scientific theories about mental illness.

Freud and the Importance of Unconscious Forces

Sigmund Freud (1856–1939), a Viennese neurologist, played a major role in making the study of psychological disorders a science. He not only developed new methods, for both diagnosis and treatment (many of which are still in use today), but also proposed a rich and intricate theory, which continues to have massive influence on many clinicians. The beginnings of Freud's contributions to the study of psychopathology can be traced to 4 months he spent studying with the French neurologist Jean-Martin Charcot (1825–1893). Charcot, a professor at the Salpêtrière hospital in Paris, treated women with hysteria, which he believed arose from abnormal neurological functioning. Charcot proposed that people with hysteria have susceptible nerves, and that their hysterical symptoms could be cured by *hypnosis*, a trancelike state of consciousness in which a person is susceptible to suggestions about his or her thoughts, feelings, and behaviors. Charcot would induce a hypnotic trance in hysterical patients and suggest that their symptoms would go away, which they often did.

Initially, Freud used hypnosis with his patients in Vienna, though he found that not everyone was equally hypnotizable and that patients' symptoms often returned. This led Freud to develop another method to help patients with hysteria: *free association*, a technique in which patients are encouraged to say whatever thoughts occur to them. Free association was part of Freud's treatment that involved talking—often referred to as the “talking cure”—which rested on his idea that hysteria (and mental disorders in general) arises in part because of unconscious conflicts. His idea was that talking freely would help a person to reduce his or her unconscious conflicts and so provide some relief from the psychological disorder.

Psychoanalytic Theory

Freud developed a far-reaching theory of the origins, nature, and treatment of psychopathology based on both his work with patients (who were mostly middle-class and upper-middle-class women with hysteria) and his observations about himself. His theory, **psychoanalytic theory** (the Greek word *psyche* means “mind”), proposes that thoughts, feelings, and behaviors are a result of conscious and unconscious forces continually interacting in the mind. Freud often discussed *motivations*, which are thoughts (such as goals), feelings (such as guilt), or a mixture of thoughts and feelings that impel one to behave in a specific way. Psychoanalytic theory also suggests that the mind is organized so as to function across three levels of consciousness:

- The *conscious* consists of thoughts and feelings that are in awareness; this is normal awareness.
- The *preconscious* consists of thoughts and feelings that a person does not perceive, but that might enter conscious awareness in the future.
- The *unconscious* includes thoughts and feelings that cannot be perceived or called into awareness on command, but which have power to influence a person.

Psychoanalytic theory

The theory that thoughts, feelings, and behaviors are a result of conscious and unconscious forces continually interacting in the mind.

Id

According to Freud, the seat of sexual and aggressive drives, as well as of the desire for immediate gratification of physical and psychological needs.

Superego

According to Freud, the seat of the conscience, which works to impose morality.

Ego

According to Freud, the psychic structure that is charged with mediating between the id's demands for immediate gratification and the superego's high standards of morality, as well as the constraints of external reality.

Psychosexual stages

According to Freud, the sequence of five distinct stages of development (oral, anal, phallic, latency, and genital) through which children proceed from infancy to adulthood; each stage has a key task that must be completed successfully for healthy psychological development.

Figure 1.2

1.2 ► The Iceberg Metaphor of the Organization of the Mind According to Freud

Freud proposed that the mind is made up of three structures: id, ego, and superego. Each individual is aware (conscious) of some of what is in his or her ego and superego; some of the preconscious contents of the ego and the superego can be brought into awareness, and some of those contents—along with all of the id—remain unconscious.

According to Freud, people have sexual and aggressive urges from birth onward. Freud argued that when we find such urges unacceptable, they are banished to our unconscious, where they inevitably gain strength and eventually demand release. Unconscious urges can be released as conscious feelings or thoughts, or as behaviors. Freud believed that abnormal experiences and behaviors arise from this process. For example, according to psychoanalytic theory, one woman's extreme fear of eating dust—which drove her to cover cooked food on the stove, not to serve food until she had brushed off her clothes and the tablecloth, and to wash her plate repeatedly to remove any speck of dust—arose from unconscious sexual impulses related to “taking in” semen (the dust symbolically represented semen; Frink, 1921).

Freud (1923/1961) also distinguished three psychological structures of the mind—the id, the ego, and the superego:

- The **id** is the seat of sexual and aggressive drives, as well as of the desire for immediate gratification of physical and psychological needs. These physical needs (such as for food and water) and psychological drives (sexual and aggressive) constantly require satisfaction. The id follows the *pleasure principle*, seeking gratification of needs without regard for the consequences.
- The **superego**, the seat of an individual's conscience, works to impose morality. According to Freud, the superego is responsible for feelings of guilt, which motivate the individual to constrain his or her sexual and aggressive urges that demand immediate gratification. People with an inflexible morality—an overly rigid sense of right and wrong—are thought to have too strong a superego.
- Meanwhile, the **ego** tries to mediate the id's demands for immediate gratification and the superego's high standards of morality, as well as the constraints of external reality. Normally, the ego handles the competing demands well. However, when the ego is relatively weak, it is less able to manage the conflicts among the id, superego, and reality, which then cause anxiety and other symptoms.

Figure 1.2 shows how the three mental structures are related to the three kinds of consciousness. As is evident, both the ego and the superego are privy to conscious thoughts, but also have access to preconscious ones (which can be called to mind voluntarily). Similarly, some aspects of both of these structures lie beneath consciousness, in the unconscious. The id is entirely in the realm of the unconscious. Thus, according to Freud, you cannot be directly aware of the basic urges that drive your thoughts, feelings, and behaviors. You only find out about these urges by observing their effects on the ego and the superego—usually in the form of conflicts. One of Freud's lasting contributions to the field of psychopathology—and all of psychology, in fact—is the notion of the unconscious, the mental processes that occur outside of our awareness and influence our motivations, thoughts, feelings, and behaviors.

Psychosexual Stages

Freud also identified five distinct stages of development (the oral, anal, phallic, latency, and genital stages) through which children proceed from infancy into adulthood. Four of these stages involve particular *erogenous zones*, which are areas of the body (the mouth, genitals, and anus) that can satisfy the id's urges and drives. Freud called these five stages **psychosexual stages** because he believed that each erogenous zone demands some form of gratification and that each stage requires a person successfully to complete a key task for healthy psychological development. All of these stages arise during infancy or childhood, although they may not be resolved until adulthood, if ever.

According to Freud, a child who fails to satisfy the needs of a psychosexual stage will develop a *fixation*, a tendency for thoughts, feelings, and behaviors to relate to that particular stage of psychosexual development, even as the child passes to the next stage. Under stress, a person with a fixation might regress to the thoughts, feelings, and behaviors of the earlier stage. For example, according to Freud (1905/1955), people with a fixation at the oral stage use food or alcohol to alleviate anxiety.

Mental Illness, According to Freud

Freud proposed two general categories of mental illness: *neuroses* and *psychoses*. A **neurosis** is a pattern of thoughts, feelings, or behaviors that expresses an unresolved conflict between the ego and the id or between the ego and the superego. One type of neurosis—what Freud called an *anxiety neurosis*—involves extreme “free-floating fear” that latches onto different objects or possibilities; people with anxiety neuroses may “interpret every coincidence as an evil omen, and ascribe a dreadful meaning to all uncertainty” (Freud, 1920, p. 344).

Freud (1938) defined *psychosis* as a break from reality characterized by conflict between the ego’s view of reality and reality itself. (Note that this is *not* the definition of *psychosis* provided earlier in this chapter; that will be the one employed throughout the rest of this book.) According to the psychoanalytic view, then, schizophrenia involves a psychosis because it is an escape from reality into one’s own internal world (Dorcus & Shaffer, 1945).

Freud was also revolutionary in proposing that parents’ interactions with their child are central in the formation of personality. For instance, parents who are too strict about toilet training their toddler may inadvertently cause their child to become fixated at the anal stage. A person who has such a fixation may develop obsessional thoughts and compulsions about being clean and orderly, as in *obsessive-compulsive disorder*, which is marked by persistent and repetitive thoughts and behaviors (American Psychiatric Association, 2000).

Defense Mechanisms

In addition to proposing an explanation for how internal psychological conflict arises, Freud, along with his daughter, the noted psychoanalyst Anna Freud (1895–1982), suggested how such conflicts are resolved: The ego frequently employs unconscious **defense mechanisms**, which work to transform the conflicts in a way that prevents unacceptable thoughts and feelings from reaching consciousness. If successful, defense mechanisms can decrease anxiety (see Table 1.3). Freud proposed several defense mechanisms, and Anna Freud extended this work. Conflicts and threats do not necessarily cause psychological disorders, but they may do so when a particular defense mechanism is relied on too heavily.

Psychoanalytic Theory Beyond Freud

Psychoanalytic theory has been modified by Freud’s followers; these variations fall under the term *psychodynamic theory* and have attracted many adherents. Psychodynamic theorists have focused on areas that Freud did not develop fully:

- normal versus abnormal development of the self (Kohut, 1971);
- the contribution of additional sources of motivation, such as feelings of inferiority (Ansbacher & Ansbacher, 1956);
- the development and work of the ego (Hartmann, 1939);

Bettmann/Corbis

In Freud’s view, mental illness is caused by unconscious conflicts that express themselves as psychological symptoms. He revolutionized treatment of psychological disorders by listening to what patients had to say.

Neurosis

According to psychoanalytic theory, a pattern of thoughts, feelings, or behaviors that expresses an unresolved conflict between the ego and the id or between the ego and the superego.

Defense mechanisms

Unconscious processes that work to transform psychological conflict so as to prevent unacceptable thoughts and feelings from reaching consciousness.

Table 1.3 ▶ Common Defense Mechanisms

Defense Mechanism	How the Defense Mechanism Transforms the Conflict	Example
Repression (considered to be the most important defense mechanism)	Unintentionally keeping conflict-inducing thoughts or feelings out of conscious awareness	You “forget” about the time you saw someone getting mugged across the street.
Denial	Not acknowledging the conflict-inducing thoughts or feelings to oneself (and others)	You are addicted to painkillers, but won’t admit it even though the addiction has caused you to miss work.
Rationalization	Justifying the conflict-inducing thoughts, feelings, or behaviors with explanations	After a father hits his daughter, he justifies his behavior to himself by saying she deserved it.
Projection	Ascribing (projecting) the conflict-inducing thoughts or feelings onto others	Instead of admitting that you don’t like a classmate, you say the person doesn’t like you.
Reaction Formation	Transforming the conflict-inducing thoughts or feelings into their opposite	Your feelings of attraction to your colleague at work are transformed into distaste and disgust, and you begin to feel repulsed by the colleague.
Sublimation	Channeling the conflict-inducing thoughts or feelings into less threatening behaviors	When a father’s frustration and anger at his teenage daughter mount, he channels his feelings by going for a 20-minute run.

- the possibility that our species has certain inborn and unconscious archetypes (an *archetype* is an abstract, ideal characterization of a person, object, or concept) that channel some aspects of motivation (Jung, 1983).

In addition, Karen Horney (1885–1952) and other psychologists conducted research on the ways that moment-to-moment interactions between child and parent can contribute to psychological disorders (Horney, 1937; Kernberg, 1986; Sullivan, 1953). This emphasis on the contribution that an infant’s social world can make to psychopathology is one of the lasting contributions of psychodynamic theory. Treatment based on psychodynamic theory is generally referred to as *psychodynamic therapy* and will be discussed in Chapter 4. Various modifications of psychodynamic therapy have been developed, based on specific alterations of Freud’s theory.

Evaluating Freud’s Contributions

One challenge to psychodynamic theory is that its guiding principles, and those of its corresponding treatments, rest primarily on subjective interpretations of what patients say and do. Another challenge is that the theory is not generally amenable to scientific testing. For instance, a fear of eating dust could be due to a sublimation of sexual impulses (a fixation at the oral stage) or a reaction formation to an unconscious desire to play with fecal matter (a fixation at the anal stage). The problem

is not that there can be more than one hypothesis based on psychodynamic theory, but rather that there is no evidence and no clear means for obtaining evidence that either hypothesis (or both) is correct.

The Humanist Response

Some psychologists, such as Abraham Maslow (1908–1970), reacted adversely to Freud's ideas, especially two notions: (1) that mental processes are mechanistic (with the same sort of cause-and-effect relations that govern all machines), driven by sexual and aggressive impulses, and (2) that humans don't really have free will because our behavior is in response to unconscious processes. These psychologists proposed a different view of human nature and mental illness that came to be called *humanistic psychology*, which focuses on free will, innate goodness, creativity, and the self (Maslow, 1968). Mental health clinicians with this outlook, such as Carl Rogers (1902–1987), are often called *humanists*. Rogers (1942) proposed that symptoms of distress and mental illness arise when a potential route to personal growth is blocked, as can occur when a person lacks a coherent and unified sense of self or when there is a mismatch—or *incongruence*—between the ideal self (the qualities a person wants to have) and the real self (the qualities the person actually has). For example, suppose a woman believes she should *always* be energetic (ideal self), but her real self is someone who is often energetic, but not always. The incongruence between the two selves can lead her to feel bad about herself, which in turn creates feelings of apathy and guilt.

Rogers developed *client-centered therapy* to help people reduce such incongruence and to help them create solutions to their problems by releasing their “real selves.” In accordance with this approach of self-empowerment, Rogers (1942) stressed that his *clients* were not *patients*, who are seen to be “sick” and lacking in power. Referring to people as “clients” indicated that they had control over their own lives and were interested in self-improvement through engagement with mental health services (Kahn, 1998).

However, although the emphasis on self-empowerment has proven useful, the humanist approach falls short as a general method for conceptualizing and treating mental illness. As we shall see, other factors (e.g., biological and social) must be considered.

Building on the humanist nomenclature, other clinicians have recognized that clients are consumers of mental health services who often choose from a variety of possible treatments. Nevertheless, it is also acceptable to use the term *patient*, and in this book we use the term *patient* and *patients* to emphasize the suffering and distress experienced by people with psychological disorders.

Lasting Contributions of Psychodynamic and Humanist Approaches

As the humanist response made clear, psychodynamic theory was not solidly rooted in science. Nevertheless, despite its limitations, psychodynamic theory rested on a fundamental insight that was crucial for the development of later theories and treatments: **Mental processes** are the internal operations that underlie cognitive and emotional functions (such as perception, memory, and guilt feelings) and most human behavior. In addition, psychodynamic theory's focus on **mental contents**—the specific memories, knowledge, goals, and other material that are stored and processed in the mind—has led to much fruitful research. Furthermore, the notion that some mental processes and mental contents are hidden away from consciousness has proven invaluable to understanding psychopathology. Psychodynamic theory is still used by some mental health clinicians to help them understand aspects of mental illness. Moreover, psychodynamic approaches cleared the way for more scientific approaches to understand psychological disorders, which we consider next.

Mental processes

The internal operations that underlie cognitive and emotional functions (such as perception, memory, and guilt feelings) and most human behavior.

Mental contents

The specific material that is stored in the mind and operated on by mental processes.

Key Concepts and Facts About The Transition to Scientific Accounts of Psychological Disorders

- Freud played a major role in making the study of psychological disorders a science, largely by developing new methods for diagnosis and treatment; he also proposed an extensive theory of psychopathology. Freud's methods included hypnosis (which he later abandoned) and free association.
- According to Freud's psychoanalytic theory, thoughts, feelings, and behaviors are a result of conscious and unconscious forces—such as sexual and aggressive urges—continually interacting in the mind. Moreover, he proposed that the mind is structured so as to function across three levels of consciousness: the conscious, the preconscious, and the unconscious. Freud stressed that many mental processes occur outside our awareness but nonetheless influence thoughts, feelings, and behaviors. Unacceptable urges are banished to the unconscious, where they inevitably gain strength and eventually demand release.
- Freud proposed three psychic structures in the mind—id, ego, and superego—which are continually interacting and negotiating. The ego frequently employs defense mechanisms to transform conflict in a way that prevents unacceptable thoughts and feelings from reaching consciousness.
- According to Freud, each individual passes through five psychosexual stages from infancy to adulthood, of which four involve particular erogenous zones. For healthy psychological development, each stage requires the successful completion of a key task; otherwise, the person will develop a fixation. Mental illness can take the form of neurosis or psychosis. Freud also proposed that parents' interactions with their child are central in forming the child's personality.
- Freud's followers focused on a variety of issues related to the development of the self and of the ego, the role of motivation, the possibility of unconscious archetypes, and the ways moment-to-moment interactions between child and parent can contribute to psychological disorders. Various forms of psychodynamic therapy have been proposed, each drawing primarily on a different aspect of psychodynamic theory. A drawback of psychodynamic theory is that it has proven difficult to test scientifically.
- Humanistic psychologists such as Carl Rogers viewed psychodynamic theory as too mechanistic and opposed to free will. Rogers proposed that symptoms of distress and mental illness arise when a potential route to personal growth is blocked, as can occur when there is incongruence between the ideal and real selves. Rogers developed client-centered therapy to decrease incongruence in clients.
- Lasting contributions of psychodynamic theory include the focus on mental processes and mental contents and the concept that such processes and contents can be hidden from awareness.

Scientific Accounts of Psychological Disorders

In the early 20th century, advances in science led to an interest in theories of psychological disorders that could be tested rigorously. Several different scientific approaches (and accompanying theories) that emerged at that time are still with us today; they focus on different aspects of psychopathology, including behavior, cognition, social forces, and biology. These scientific accounts and theories have thrived because studies have shown that they explain some aspects of mental illness. Let's examine these modern approaches to psychopathology and how they could explain Big Edie and Little Edie's lifestyle.

Behaviorism

All of the views discussed so far focus on forces that affect mental processes and mental contents. However, some psychologists in the early 20th century took a radically different perspective and focused on directly observable behaviors. Spearheaded by American psychologists Edward Lee Thorndike (1874–1949), John B. Watson (1878–1958), and Clark L. Hull (1884–1952), and, most famously, B. F. Skinner (1904–1990), **behaviorism** focuses on understanding directly observable behaviors rather than unobservable mental processes and mental contents (Watson, 1931). The behaviorists' major contribution to understanding psychopathology was to propose scientifically testable mechanisms that may explain how maladaptive behavior arises (Skinner,

Behaviorism

The approach to psychology that focuses on understanding directly observable behaviors in order to understand mental illness and other psychological phenomena.

1986, 1987). These psychologists focused their research on the association between a behavior and its consequences—factors that influence whether a behavior is likely to recur. For instance, to the extent that using a drug has pleasurable consequences, an individual is more likely to use the drug again.

At about the same time in Russia, Nobel-Prize-winning physiologist Ivan Pavlov (1849–1936) accidentally discovered an association between a reflexive behavior and its antecedents, an association created by a process sometimes referred to as *Pavlovian conditioning* (Pavlov, 1936). He studied salivation in dogs, and he noticed that dogs increased their salivation both while they were eating (which he predicted—the increased salivation when eating is a reflexive behavior) and *right before* they were fed (which he did not predict). After investigating why this latter salivation might occur, he determined that the dogs began salivating when they heard the approaching footsteps of the person feeding them. The feeder's footsteps (a neutral stimulus) became associated with the stimulus of food in the mouth, thus leading the dogs to salivate when hearing the sound of footsteps; the dogs' past association between the feeder's footsteps and subsequent food led to a behavior change.

Pavlov investigated the reflexive behavior of salivation, but other researchers have found that reflexive fear-related behaviors (such as a startle response) can be conditioned in the same fashion. These findings contributed to the understanding of how the severe fears and anxieties that are part of many psychological disorders can arise—how neutral stimuli that have in the past been paired with fear-inducing objects or events can, by themselves, come to induce fear or anxiety. We will consider such conditioning in more detail in Chapter 2.

Among the most important insights of behaviorism, then, is that a person's behavior, including maladaptive behavior, can result from learning—from a previous association with an object, situation, or event. Big Edie appears to have developed maladaptive behaviors related to a fear of being alone. This may have been a result of past negative experiences with (and the resulting associations to) being alone. The behaviorist approach has also accounted for some aspects of substance abuse, including alcoholism, which can arise because of the association between drinking and feeling more relaxed soon after drinking: Based on past experiences with alcohol, someone who wants to become less tense may reach for a bottle. Behaviorists have discovered different ways that associations can be learned, and each sort of learning can affect psychological disorders (we will discuss forms of learning in Chapter 2 and treatments based on these forms of learning in Chapter 4).

Behaviorism ushered in new explanations of—and treatments for—some psychological disorders, but researchers soon learned that not all psychological problems could readily be explained as a result of maladaptive learning. Rather, mental processes and mental contents are clearly involved in the development and maintenance of many psychological disorders. The behaviorists' emphasis on controlled, objective observation and on the importance of the situation, however, had a deep and lasting impact on the field of psychopathology.

The Cognitive Contribution

Psychodynamic and behaviorist explanations of psychological disorders seemed incompatible. Psychodynamic theory emphasized private mental processes and mental contents; behaviorist theories emphasized directly observable behavior. Then, the late 1950s and early 1960s saw the rise of *cognitive psychology*, the area of psychology that studies mental processes starting from the analogy of information processing by a computer. Researchers developed new, behaviorally based methods to track the course of hidden mental processes, and these mental processes began to be demystified. If a mental process is like a computer program, direct connections can be made between observable events (such as changes in the time it takes to respond to different stimuli) and mental processes.

ImageState/Alamy

Behaviorism focuses on observable behaviors and their consequences. According to behaviorists, maladaptive behaviors that are related to psychological disorders, such as drinking too much alcohol, can arise because the pleasurable consequences of the behavior lead people to want to engage in it again.

Cognitive psychology has contributed to the understanding of psychological disorders by focusing on specific changes in mental processes. For instance, people with *anxiety disorders*—a category of disorders that involves extreme fear, panic, and/or avoidance of a feared stimulus—tend to focus their attention in particular ways, creating a bias in what they expect and remember. In turn, these biased memories appear to support the “truth” of their inaccurate view about the danger of the stimulus that elicits their fear. For instance, a man who is very anxious in social situations may pay excessive attention to whether other people seem to be looking at him; when people glance in his general direction, he will then notice the direction of their gaze and infer that they are looking at him. Later, he will remember that “everyone” was watching him.

Other cognitive explanations of psychological disorders focused on the content of people’s thoughts. Psychiatrist Aaron Beck (b. 1921) and psychologist Albert Ellis (1913–2007) each focused on how people’s irrational and inaccurate thoughts about themselves and the world can contribute to psychological disorders (Beck, 1967; Ellis & Maclaren, 1998). For example, people who are depressed often think very negatively and inaccurately about themselves, the future, and the world. They think that they are inept, ugly, or unlovable or they have other equally unhappy thoughts. They often believe that they will *always* be so, and that no one will care about them; or, if someone does care, this person will leave as soon as he or she sees how really inept, ugly, or unlovable the depressed person is. Such thoughts could make anyone depressed! For cognitive therapists, treatment involves shifting, or *restructuring*, people’s faulty beliefs and irrational thoughts that led to psychological disorders. Such cognitive techniques will be discussed in more detail in Chapter 4.

Cognitive therapy might have been appropriate for the Beale women, who had unusual beliefs. Consider the fact that Little Edie worried about leaving her mother alone in her room for more than a few minutes because she might come back and find her mother dead, or that a stranger might break in, despite the fact that the windows were nailed shut (Graham, 1976). Big Edie also had unusual beliefs. One time, a big kite was hovering over Grey Gardens and she called the police, concerned that the kite was a listening device or a bomb (Wright, 2007).

The focus on particular mental processes and mental contents illuminates some aspects of psychological disorders. But just as behaviorist theories do not fully address why individuals develop the *particular* beliefs and attitudes they have, cognitive theories do not fully explain why an individual’s mental processes and contents are biased in a *particular* way. For instance, Little Edie’s brothers, who grew up in the same household, were not eccentric, nor did they appear to harbor unusual beliefs or behave in bizarre ways. Knowledge about social and neurological factors (i.e., those that affect the brain and its functioning) helps to complete the picture.

Social Forces

We can view behavioral and cognitive explanations as psychological: Both refer to thoughts, feelings, or behaviors of individuals. In addition to these sorts of factors, we must also consider social factors, or factors that involve more than a single person. There is no unified social explanation for psychological disorders, but various researchers and theorists in the last half of the 20th century recognized that social forces affect the emergence and maintenance of mental illness. Many of these social forces, such as the loss of a relationship, abuse, trauma, neglect, poverty, and discrimination, produce high levels of stress.

Looking at the earliest years of life, Freud had a valuable insight when he recognized that the way parents treat their children can make them more vulnerable to mental illness. Two researchers who focused on the interactions between the infant and the primary caretaker were John Bowlby (1969) and Mary Ainsworth (1989; Ainsworth & Bell, 1970). They examined *attachment style*, which characterizes the particular way a person relates to intimate others. Specifically, they observed young American children with their mothers and characterized each child’s attachment style

by noting his or her behavior when the mother briefly left the room. Researchers have delineated four types of attachment styles:

1. *Secure attachment*. These children became upset when their mother left, but quickly calmed down upon her return (Ainsworth & Bell, 1970).
2. *Resistant/anxious attachment*. These children became angry when their mother left and remained angry upon her return, sometimes even hitting her (Ainsworth & Bell, 1970).
3. *Avoidant attachment*. These children had no change in their emotions based on mother's presence or absence (Ainsworth & Bell, 1970).
4. *Disorganized attachment*. These children exhibited a combination of resistant and avoidant styles, and also appeared confused or fearful with their mother (Main & Solomon, 1986).

Children who did not have a secure attachment style (those with a resistant/anxious, avoidant, or disorganized style) were more likely to develop symptoms of psychological disorders (Main & Solomon, 1986; Minde, 2003). However, attachment styles can be different in different cultures; these four attachment styles and their association with psychological disorders are not necessarily accurate descriptions of attachment styles for all cultures or countries (Rothbaum et al., 2000).

Research on social factors also points to the ways that relationships—and the social support they provide—can buffer the effects of negative life events (Hyman, Gold, & Cott, 2003; Swift & Wright, 2000). For example, researchers have found that healthy relationships can mitigate the effects of a variety of negative events, such as abuse (during childhood or adulthood), trauma, discrimination, and financial hardship. The converse is also true: The absence of protective relationships increases an individual's risk for developing a psychological disorder in the face of a significant stressor (Dikel, Engdahl, & Eberly, 2005). (Note that *stressor* is the technical term used to refer to any stimulus that induces stress.)

The Beale women experienced many stressors: financial problems, the dissolution of Phelan and Big Edie's marriage, and, in later years, social isolation. Their extended family and their community ostracized them, at least in part because they were independent-minded and artistic women. In addition, Little Edie endured her own unique social stresses: Both her parents were excessively controlling, though in different ways. Her father restricted her artistic pursuits. And Little Edie could scarcely leave her mother's room before her mother was calling urgently for her to return; this intense attachment and close physical proximity echo their relationship when Little Edie was a child.

Like the other factors, social factors do not fully account for how and why psychological disorders arise. For instance, social explanations cannot tell us why, of people who experience the same circumstances, some will go on to develop a psychological disorder and others won't.

Biological Explanations

As some researchers explored the behavioral, cognitive, and social factors that contribute to psychological disorders and their treatment, other researchers continued to focus on biological causes of psychological disorders and their medical treatments. Many biological researchers were impressed by the discovery in 1913 that one type of mental illness—which was then called *general paresis*, or *paralytic dementia*—was caused by a sexually transmitted disease, syphilis. The final stage of this disease damages the brain and leads to abrupt changes in mental processes, including psychotic symptoms (Hayden, 2003). The discovery of a causal link between syphilis and general paresis heralded a resurgence of the medical model, the view that psychological disorders have underlying biological causes. According to the

Children who do not have a secure attachment style have a higher likelihood of subsequently developing symptoms of psychological disorders (Main & Solomon, 1986; Minde, 2003).

Michael Newman/Photo Edit

The bacterium *Treponema pallidum* is responsible for the sexually transmitted disease syphilis. Left untreated, syphilis eventually causes severe brain damage that in turn gives rise to abrupt changes in mental processes, including psychotic symptoms.

medical model, once the biological causes are identified, appropriate medical treatments can be developed, such as medications. In fact, antibiotics that treat syphilis also prevent the related mental illness, which was dramatic support for applying the medical model to at least some psychological disorders.

Since that discovery, scientists have examined genes, neurotransmitters (chemicals that allow brain cells to communicate with each other), and abnormalities in brain structure and function associated with mental illness. However, explaining psychological disorders simply on the basis of biological factors ultimately strips mental disorders of the context in which they occur—in thinking people who live in families and societies—and provides a false impression that mental disorders arise from biological factors alone. As we shall see throughout this book, multiple factors usually contribute to a psychological disorder, and treatments targeting only biological factors are not necessarily the most effective.

What biological factors might have contributed to the Beales' unusual lifestyle and beliefs? Unfortunately, the documentaries and biographies about the two women have not addressed this issue, so there is no way to know. All we know is that one of Big Edie's brothers was a serious gambler, another died as a result of a drinking problem, and one of her nieces also battled problems with alcohol; taken together, these observations might suggest a family history of impulse control problems. We might be tempted to infer that such tendencies in this family reflect an underlying genetic predisposition, but we must be careful: Families share more than their genes, and common components of the environment can also contribute to psychological disorders.

The Modern Synthesis of Explanations of Psychopathology

In the last several decades, researchers and clinicians increasingly recognize that psychological disorders cannot be fully explained by any single type of factor or theory. Two approaches to psychopathology integrate multiple factors: the *diathesis–stress model* and the *biopsychosocial approach*.

Figure 1.3

The Diathesis–Stress Model

The diathesis–stress model is one way to bring together the various explanations of how psychological disorders arise. The **diathesis–stress model** rests on the claim that a psychological disorder is triggered when a person with a predisposition—a *diathesis*—for the particular disorder experiences an environmental event that causes significant stress (Meehl, 1962; Monroe & Simons, 1991; Rende & Plomin, 1992). Essentially, the idea is that if a person has a predisposition to a psychological disorder, stress may trigger its occurrence. But the same stress would not have that effect for a person who did not have the predisposition; also, a person who did have a diathesis for a psychological disorder would be fine if he or she could avoid high-stress situations. Both factors are required. For example, the diathesis–stress model explains why, if one identical twin develops depression, the co-twin (the other twin of the pair) also develops depression in less than a quarter of the cases (Lyons et al., 1998). Because identical twins share 100% of their genes, a co-twin should be virtually guaranteed to develop the disorder if genes alone cause it to develop. But even identical twins experience different types and levels of stress. Their genes are identical, but their environments are not; thus, both twins do not necessarily develop the psychological disorder over time. The diathesis–stress model is illustrated in Figure 1.3.

A diathesis may be a biological factor, such as a genetic vulnerability to a disorder, or it may be a psychological factor, such as a cognitive vulnerability to disorder, such as can occur when irrational or inaccurate negative thoughts about oneself contribute to depression. The *stress* is often a social factor, which can be acute, such as being the victim of a crime, or less intense but chronic, such as recurring spousal abuse, poverty, or overwork. It is important to note that not

1.3 ► The Diathesis–Stress Model

According to the diathesis–stress model of depression, people who are more vulnerable to depression (high diathesis) will become depressed after experiencing less stress than people who are less vulnerable to depression (low or absent diathesis). Put another way, given the same level of stress, those who are more vulnerable to depression will develop more symptoms of depression than those who are less vulnerable.

everybody experiences the same social factor in the same way. And what's important is not simply the objective circumstance; it's how a person perceives it. For example, think about roller coasters: For one person, they are great fun; for another, they are terrifying. Similarly, Big Edie and Little Edie didn't appear to mind their isolation and strange lifestyle and may even have enjoyed it; other people, however, might find living in such circumstances extremely stressful and depressing. Whether because of learning, biology, or an interaction between them, some people are more likely to perceive particular events and stimuli as stressors (and therefore to experience more stress) than others. The diathesis–stress model was the first approach that integrated existing, but separate, explanations for psychological disorders.

The Biopsychosocial and Neuropsychosocial Approaches

To understand the bases of both diatheses and stress, we need to look more carefully at the factors that underlie psychological disorders.

Three Types of Factors

Historically, researchers and clinicians grouped the factors that give rise to psychological disorders into three general types: *biological* (including genetics, the structure and function of the brain, and the function of other bodily systems); *psychological* (thoughts, feelings, and behaviors); and, *social* (social interactions and the environment in which they occur). The **biopsychosocial approach** to understanding psychological disorders rests on identifying these three types of factors and documenting the ways in which each of them contributes to a disorder.

That is, the biopsychosocial approach leads researchers and clinicians to look for ways in which the three types of factors contribute to both the diathesis (the predisposition) and the stress. For instance, having certain genes (a biological factor), having biases to perceive certain situations as stressful (a psychological factor), and living in poverty (a social factor) all can contribute to a diathesis; similarly, chronic lack of sleep (a biological factor), feeling that one's job is overwhelming (a psychological factor), or having a spouse who is abusive (a social factor) can contribute to stress.

However, two problems with the traditional biopsychosocial approach have become clear. First, the approach does not specifically focus on the organ that is responsible for cognition and affect, that allows us to learn, that guides behavior, and that underlies all conscious experience—namely, the brain. The brain not only gives rise to thoughts, feelings, and behaviors, but also mediates all other biological factors; it both registers events in the body and affects bodily events.

Second, sometimes the biopsychosocial approach was used to identify a set of factors that together caused a disorder. However, the factors were often considered in isolation, as if they were items on a list. Considering the factors in isolation is reminiscent of the classic South Asian tale about a group of blind men feeling different parts of an elephant, each trying to determine what the animal is. One person feels the trunk, another the legs, another the tusks, and so on, and each reaches a different conclusion. Even if you combined all the people's separate reports, you might miss the big picture of what an elephant is: That is, an elephant is more than a sum of its body parts; the parts come together to make a dynamic and wondrous creature.

We are beginning to understand how the three types of factors combine and affect each other. That is, factors that researchers previously considered to be independent are now known to influence each other. For example, the way that parents treat their infant was historically considered to be exclusively a social factor—the infant was a receptacle for the caregiver's style of parenting. However, more recent research has revealed that parenting style is in fact a complex set of interactions between

The whole elephant cannot be described by a group of blind men if each of them is feeling only a small part of the animal's body. In the same way, past explanations of psychological disorders that focused on only one or two factors created an incomplete understanding of such disorders.

Diathesis–stress model

The model that proposes that a psychological disorder is triggered when a person with a predisposition—a diathesis—for the particular disorder experiences an environmental event that causes significant stress.

Biopsychosocial approach

The view that a psychological disorder arises from the combined influences of three types of factors—biological, psychological, and social.

caregiver and infant. Consider that if the infant frequently fusses, this will elicit a different pattern of responses from the caregiver than if the infant frequently smiles; if the infant is fussy and “difficult,” the caregiver might handle him or her with less patience and warmth than if the infant seems happy and easy-going. And the way the caregiver handles the infant in turn affects how the infant responds to the caregiver. In turn, these early interactions between child and caregiver (a social factor) contribute to a particular attachment style, which is associated with particular biases in paying attention to and perceiving emotional expressions in faces (psychological factors; Fraley & Shaver, 1997; Maier et al., 2005).

In fact, some researchers who championed the biopsychosocial approach acknowledged that explanations of psychological disorders depend on the interactions of biological, psychological, and social factors (Engel, 1977, 1980). But these researchers did not have the benefit of the recent advances in understanding the brain, and hence were not able to specify the nature of such interactions in much detail.

These two problems led to a revision of the traditional biopsychosocial approach, to align it better with recent discoveries about the brain and how psychological and social factors affect brain function. We call this updated version of the classic approach the *neuropsychosocial approach*, which is explained in the following section.

The Neuropsychosocial Approach: Refining the Biopsychosocial Approach

The neuropsychosocial approach has two defining features: the way it characterizes the factors and the way it characterizes their interactions. As we discuss below, this approach emphasizes the brain rather than the body (hence the *neuro-* in its name) and maintains that no factor can be considered in isolation.

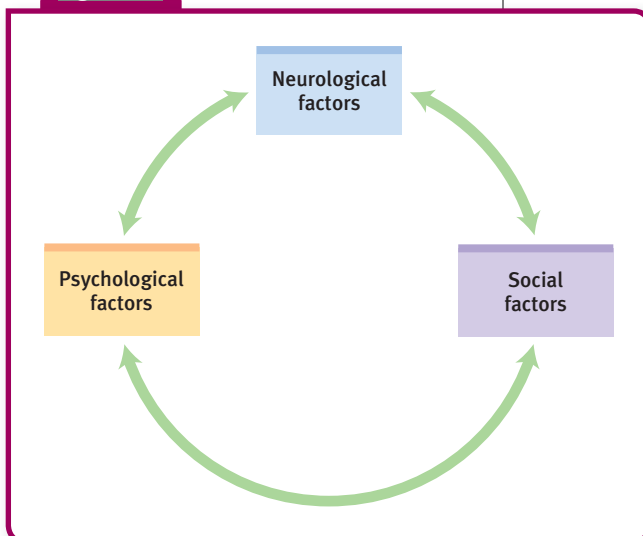

Emphasis on the Brain. As psychologists and other scientists have learned more about the biological factors that contribute to psychological disorders, the primacy of the role of the brain—and even particular brain structures and functions—in contributing to psychological disorders has become evident. Ultimately, even such disparate biological factors as genes and bodily responses (e.g., the increased heart rate associated with anxiety) are best understood in terms of their relationship with the brain.

Because of the importance of the brain’s influence on all biological functioning involved in psychological disorders, this book generally uses the term *neurological* rather than *biological* and the term *neuropsychosocial* rather than *biopsychosocial* to refer to the three types of factors that contribute to psychological disorders.

Emphasis on Feedback Loops. In addition, neurological, psychological, and social factors are usually involved simultaneously and are constantly interacting (see Figure 1.4). These interactions occur through feedback loops: Each factor is affected by the others, and *also* feeds back to affect the other factors. Hence, no one factor can be understood in isolation, without considering the other factors. For example, problems in relationships (social factor) can lead people to experience stress (psychological factor); in turn, when people feel stressed, their brains cause their bodies to respond with a cascade of events.

As you will see throughout this book, interactions among neurological, psychological, and social factors are common. Icons that look like this will highlight parts of the text that illustrate specific ways that these factors interact with one another:

Figure 1.4

1.4 ► The Neuropsychosocial Approach

According to the neuropsychosocial approach, neurological, psychological, and social factors *interact with one another* via feedback loops to contribute to the development of psychopathology.

- indicates feedback between neurological and psychological factors: 
- indicates feedback between neurological and social factors: 
- indicates feedback between psychological and social factors:  and
- indicates feedback among all three pairs of factors: 

Such icons will be in the margin of the page; the relevant portion of text will also be highlighted in the margin. Any of the types of factors can spark us to behave in a certain way or can help us control ourselves so that we do *not* behave in a certain way.

In short, the **neuropsychosocial approach** can allow us to understand how neurological, psychological, and social factors—which affect and are affected by one another through feedback loops—underlie psychological disorders.

In the next chapter, we will discuss the neuropsychosocial approach to psychological disorders in more detail, examining neurological, psychological, and social factors as well as the feedback loops among them. In that chapter, we will also continue our evaluation of the Beales and the specific factors that might contribute to their unusual behavior. In subsequent chapters, we will consider the stories of various other people.

Chapters 2 through 5 will provide you with knowledge to understand psychopathology in general: neurological, psychological, and social factors that contribute to psychological disorders (Chapter 2); issues related to diagnosing and assessing psychopathology (Chapter 3); treating psychological disorders (Chapter 4); and researching psychological disorders (Chapter 5). Chapters 6 through 15 address specific categories of psychological disorders (such as anxiety disorders). The final chapter (Chapter 16) discusses ethical and legal issues related to psychological disorders.

As you will see in these subsequent chapters, the definition of a psychological disorder provided earlier in this chapter—a pattern of thoughts, feelings, or behaviors that causes significant distress, impaired functioning in daily life, and/or risk of harm—forms the basis for the definitions of specific disorders. However, we note in Chapter 3 and other chapters that the extent of distress, impaired functioning, and/or risk of harm that is required for a diagnosis of a psychological disorder is not always clear. Rather, each of these three elements exists on a continuum. Two individuals with psychological disorders are likely to have symptoms that reflect different locations on each continuum.

Neuropsychosocial approach

The view that a psychological disorder arises from the combined influences of neurological, psychological, and social factors—which affect and are affected by one another through feedback loops.

Key Concepts and Facts About Scientific Accounts of Psychological Disorders

- Psychologists Edward Thorndike, John Watson, Clark Hull, and B. F. Skinner spearheaded behaviorism, focusing on directly observable behaviors rather than unobservable mental processes and mental contents. They investigated the association between a behavior and its consequence, and proposed scientifically testable mechanisms to explain how maladaptive behavior arises. Behaviorism helps explain how maladaptive behavior can arise from previous associations with an object, situation, or event. Behaviorism led to innovative treatments.
- Ivan Pavlov discovered and investigated what is sometimes referred to as Pavlovian conditioning—the process whereby a reflexive behavior comes to be associated with a stimulus that precedes it. Pavlovian conditioning helps explain the severe fears and anxieties that are part of some psychological disorders: Neutral stimuli that have in the past been paired with fear-inducing objects or events can subsequently, by themselves, induce fear or anxiety.
- Cognitive psychology has led to the scientific investigation of mental processes that affect how people pay attention to stimuli and develop biases in what they expect and remember. Such biases in turn can confirm the inaccurate views that perpetuate a psychological disorder. Aaron Beck and Albert Ellis each focused on how people's irrational and inaccurate thoughts about themselves and the world can contribute to psychological disorders, and each developed a type of treatment to address the irrational and inaccurate thoughts.
- Social forces that help explain psychological disorders include difficulties with attachment and the role of relationships in buffering negative life events.
- The discovery of the biological cause of one type of mental illness—general paresis—led to investigations into possible biological causes of other types of mental illness. Although researchers investigate various biological and neurological abnormalities to understand psychopathology, exclusively biological explanations ultimately strip mental disorders of the context in which they occur and provide a false impression that mental disorders arise from biological (primarily neurological) factors alone.
- Psychological disorders cannot be fully explained by any single type of factor or theory. One approach to integrating different factors is the diathesis–stress model, which proposes that if a person has a predisposition to a psychological disorder, stressors may trigger its occurrence.
- The biopsychosocial approach rests on the idea that both diathesis and stress can be grouped into three types of factors: biological, psychological, and social. As research on biological factors associated with psychological disorders has advanced, the important effects of the brain on other biological functions have become clear. In addition, recent research allows investigators to begin to understand the feedback loops among the three types of factors. For these reasons, this book uses the term *neuropsychosocial* rather than *biopsychosocial*.

SUMMING UP

Summary of The Three Criteria for Defining Psychological Disorders

A psychological disorder is a pattern of thoughts, feelings, or behaviors that causes significant distress, impaired functioning in daily life, and/or risk of harm. The distress involved in a psychological disorder is out of proportion to the situation.

Impairment in daily life may be evident in functioning at school, at work, at home, or in relationships. Moreover, people with a psychological disorder are impaired to a greater degree than most people in a similar situation. A psychosis is a relatively easily identifiable type of impairment that includes hallucinations or delusions. A psychological disorder may lead to behaviors that create a significant risk of harm to the person or to others.

Mental health clinicians and researchers recognize that context and culture in part determine whether a person's state involves significant distress, impairment, or risk of harm. In particular, people from different cultures may express distress differently, and some sets of symptoms, such as those of possession trance, may, in fact, not be a disorder in certain cultures.

Thinking like a clinician

Suppose Pietro was hearing the voice of a deceased relative, and he was from a culture where such experiences were considered normal—or at least not abnormal. But he was distressed about hearing the voice, to the point where he was having a hard time doing his job. Should Pietro be considered to have a psychological disorder? If so, why? If not, why not? What additional information would you want to help you decide, if you weren't sure?

Summary of Views of Psychological Disorders Before Science

The oldest known view of psychopathology is that it arose from supernatural (magical or spiritual) forces. Treatment included exorcism. The ancient Greeks attributed mental illness to an imbalance of bodily humors. The term *medical model* refers to Hippocrates' view that illness (including psychological disorders) arises from a biological disturbance.

The Middle Ages saw a resurgence of the view that supernatural forces cause

psychopathology. This view persisted into the Renaissance, when mental illness was viewed as the result of demonic possession, and witches were thought to be possessed by, or in league with, the devil. Treatment of the mentally ill consisted of exorcism. By the end of the Renaissance, however, the mentally ill began to be treated more humanely, and asylums were built throughout Europe; over time, however, these asylums became a place to keep the mentally ill poor off the street, which led to overcrowded facilities.

In the years immediately following the Renaissance, mental illnesses were thought to arise from irrational thinking, but this approach did not lead to consistent cures.

Beginning in the 1790s, Pinel championed humane treatment for those in asylums in France. Based on careful observation, he proposed that there were different types of madness. In other European settings, patients were given moral treatment, which centered on having them live and work within a community in the countryside.

In the United States, Benjamin Rush initiated the effort to treat the mentally ill more humanely; similarly, Dorothea Dix strove to ensure that the mentally ill were housed separately from criminals and treated humanely. However, public institutions for the mentally ill became overcrowded and underfunded. By the end of the 19th century in Europe and North America, "madness" was generally viewed as caused by a medical abnormality.

Thinking like a clinician

Why might explanations of mental illness as arising from supernatural forces have been popular for so long? How does prevailing treatment of abnormality follow from beliefs about the cause of mental illness? Use specific examples.

Summary of The Transition to Scientific Accounts of Psychological Disorders

Freud played a major role in making the study of psychological disorders a science, largely by developing new methods for diagnosis and treatment; he also proposed an extensive theory of psychopathology. According to Freud's psychoanalytic theory, thoughts, feelings, and behaviors are a result of conscious and unconscious forces—such as sexual and aggressive urges—continually interacting in the mind. Moreover, he proposed that the mind is

structured so as to function across three levels of consciousness: the conscious, the preconscious, and the unconscious. Freud stressed that many mental processes occur outside our awareness but nonetheless influence thoughts, feelings, and behaviors. Unacceptable urges are banished to the unconscious, where they inevitably gain strength and eventually demand release.

Freud proposed three psychic structures in the mind—id, ego, and superego—which are continually interacting and negotiating. According to Freud, each individual passes through five psychosexual stages from infancy to adulthood, of which four involve particular erogenous zones. For healthy psychological development, each stage requires the successful completion of a key task. Freud also proposed that parents' interactions with their child are central in forming the child's personality.

Freud's followers focused on a variety of issues related to the development of the self and of the ego, the role of motivation, the possibility of unconscious archetypes, and the ways moment-to-moment interactions between child and parent can contribute to psychological disorders. A drawback of psychodynamic theory is that it has proven difficult to test scientifically.

Humanistic psychologists such as Carl Rogers viewed psychodynamic theory as too mechanistic and opposed to free will. Rogers proposed that symptoms of distress and mental illness arise when a potential route to personal growth is blocked, as can occur when the ideal and real selves are incongruent. Rogers developed client-centered therapy to decrease incongruence in clients.

Lasting contributions of psychodynamic theory include the focus on mental processes and mental contents and the concept that such processes and contents can be hidden from awareness.

Thinking like a clinician

Based on what you have read, why do you think Freud's theory has diminished in influence? Why have certain aspects of psychodynamic theory continued to influence modern perspectives?

Summary of Scientific Accounts of Psychological Disorders

Psychologists Edward Thorndike, John Watson, Clark Hull, and B. F. Skinner spearheaded behaviorism, which focused on directly

observable behaviors rather than unobservable mental processes and mental contents. They investigated the association between a behavior and its consequence, and proposed scientifically testable mechanisms to explain how maladaptive behavior arises. Behaviorism helps explain how maladaptive behavior can arise from previous associations with an object, situation, or event. Behaviorism led to innovative treatments.

Ivan Pavlov discovered and investigated what is sometimes referred to as Pavlovian conditioning—the process whereby a reflexive behavior comes to be associated with a stimulus that precedes it. Pavlovian conditioning helps explain the severe fears and anxieties that are part of some psychological disorders.

Cognitive psychology has led to the scientific investigation of mental processes that affect how people pay attention to stimuli and develop biases in what they expect and remember. Such biases in turn can confirm the inaccurate views that perpetuate a psychological disorder. Aaron Beck and Albert Ellis each focused on how people's irrational and inaccurate thoughts about themselves and the world can contribute to psychological disorders, and each developed a type of treatment to address the irrational and inaccurate thoughts.

Social forces that help explain psychological disorders include difficulties with attachment and the role of relationships in buffering negative life events.

The discovery of the biological cause of one type of mental illness—general paresis—led to investigations into possible biological causes of other types of mental illness.

However, psychological disorders cannot be fully explained by any single type of factor or theory. One approach to integrating different factors is the diathesis–stress model, which proposes that if a person has a predisposition to a psychological disorder, stressors may trigger its occurrence.

The biopsychosocial approach proposes that both diathesis and stress can be grouped into three types of factors: biological, psychological, and social. As research on biological factors associated with psychological disorders has advanced, the important effects of the brain on other biological functions have become clear. In addition, recent research allows investigators to begin to understand the feedback loops among the three types of factors. For these reasons, this book uses the term *neuropsychosocial* rather than *biopsychosocial*.

Thinking like a clinician

Natasha's uncle Alex was severely depressed about 5 years ago—to the point where he went into the hospital for a week. Natasha's parents had talked about Uncle Alex having a “chemical imbalance.” Based on what you have read, which of the various modern perspectives were her parents adopting? If her parents had used other modern perspectives to explain Alex's depression, to what would they have attributed his depression? Be specific.

How would the two integrationist approaches (diathesis–stress and biopsychosocial) explain Alex's depression? (*Hint:* Use Figures 1.3 and 1.4 to guide your answers.) What do the two approaches have in common, and in what ways do they differ from each other?

Key Terms

Abnormal psychology (p. 4)

Psychological disorder (p. 4)

Psychosis (p. 6)

Hallucinations (p. 6)

Delusions (p. 6)

Culture (p. 8)

Asylums (p. 14)

Moral treatment (p. 15)

Psychoanalytic theory (p. 17)

Id (p. 18)

Superego (p. 18)

Ego (p. 18)

Psychosexual stages (p. 18)

Neurosis (p. 19)

Defense mechanisms (p. 19)

Mental processes (p. 21)

Mental contents (p. 21)

Behaviorism (p. 22)

Diathesis–stress model (p. 27)

Biopsychosocial approach (p. 27)

Neuropsychosocial approach (p. 29)

Understanding Psychological Disorders:

The Neuropsychosocial Approach

During the last year of Big Edie's life, the Beale women had a guest, Lois Wright, stay with them. Lois slept in a spare bedroom, on a canvas cot that she had brought with her. However, the floor of her room was so thoroughly layered with years of cat droppings and fleas that she put newspaper down on the floor every night before she went to bed.

Sometimes, when Lois wanted to leave the house and go into town for her own food or supplies, the Beales wouldn't let her out. They were afraid that if they unlocked the door for Lois, a "spy might try to gain entrance" (Wright, 2007, p. 35) or Lois might be kidnapped while in town, by people wanting information about Grey Gardens.

As we saw in Chapter 1, clearly the Beale women had odd thoughts and feelings and engaged in unusual behaviors. As we asked in Chapter 1, were they merely eccentric? Did Big Edie or Little Edie (or both of them) have a psychological disorder? Could either of them have had more than one psychological disorder? If one or both had a disorder, how could we understand why? The neuropsychosocial approach allows us to consider the factors that lead someone to develop a psychological disorder, which is known as its **etiology**.

Let's consider the Beale women in terms of the neuropsychosocial approach. First, we can ask about *neurological* factors: Was something abnormal about their genes or brains? Perhaps their neurons or neurotransmitters functioned abnormally, and that led to their odd behavior. Second, we can ask about *psychological* factors: How might their thoughts and feelings have motivated them, and what role might their mental processes have played? For instance, might Pavlovian conditioning have been involved in Big Edie's apparent fear of being alone? And third, we can ask about *social* factors, such as their financial circumstances, their family relationships, the straight-laced society they were members of, and other cultural forces affecting them. To what extent might the disdain shown to Big Edie and Little Edie by their extended family have influenced their unusual behavior?

At any moment in a day of the Beales' lives (or anyone's life, for that matter), all three types of factors are operating: neurological, psychological, and social. Depending on the state of a person's brain (which is affected, for example, by various chemicals produced by the body), social factors (such as an angry friend or a stressful job interview) have a greater or lesser impact. This impact in turn affects psychological factors (the person's thoughts, feelings, and behaviors) in different ways. And then the psychological factors can affect both

Feedback Loops in Action: Learned Helplessness

Etiology

The factors that lead a person to develop a psychological disorder.

neurological factors and social factors, continuing the interaction among these different influences. Thus, considering only one type of factor would lead to an incomplete understanding of psychological disorders. That is why we consider each type of factor—neurological, psychological, and social—in detail in this chapter, to provide information that we will use in later chapters as we probe the etiology of specific psychological disorders. It is important to note, however, that the neuropsychosocial approach does not focus on each type of factor individually; rather, we must always consider how the three factors interact and affect one another via feedback loops.

Neurological Factors in Psychological Disorders

Big Edie had always been unconventional. She didn't seem to care what other people thought of her behavior. And although she loved performing—seemingly to the point of compulsion—she was a recluse for most of her adult life, seeing almost no one but her children. How did such a lifestyle arise? And what about Little Edie's paranoid beliefs? Could neurological factors account for the odd beliefs and behaviors of this mother and daughter? In fact, accumulating research indicates that genes can contribute to the development of disorders by affecting both the structure and function of the brain (Hasler et al., 2004; Gottesman, 1991; Greenwood & Kelsoe, 2003).

Neurological factors that contribute to psychological disorders include abnormalities in the structure of the brain, in the operations of specific chemicals (such as those that affect transmission of information among brain cells), and in specific genes. Researchers and clinicians sometimes focus on neurological factors when they explain psychopathology—noting, for example, that depression is correlated with abnormal levels of a particular chemical (serotonin) in the brain, or that an irrational fear of spiders develops partly from an overly reactive brain structure involved in fear (the amygdala; Larson et al., 2006). However, as you know, the neuropsychosocial approach maintains that explanations based on neurological factors alone rarely provide the whole story. For instance, one person's serotonin levels might become abnormal because of his social position (Raleigh et al., 1984), and another person's amygdala might be overly reactive because of her experiences with threatening people (Phelps et al., 2000). Each thought, feeling, and behavior, as well as each social experience and the environment in which we live and work, affects our neurological functioning. In other words, as noted above, the three types of factors typically interact with one another through *feedback loops*. Neurological factors contribute to psychopathology, but they must be considered in the context of the other factors.

To understand the role of neurological factors in explanations of psychopathology, we next consider brain structure and function, neurons and neurotransmitters, and genetics and the ways that genes interact with the environment.

Brain Structure and Brain Function

Have you ever been high in the mountains and looked up at a crystal clear night sky? The number of stars is staggering. In fact, there are about 100 billion stars in our galaxy—which nicely approximates the number of brain cells in each of our brains. Think of packing all those points of light into a single skull! And just as the stars in a galaxy are organized into clusters and arms, and the entire ensemble turns majestically around the galactic core, our billions of brains cells are organized into brain structures that work together in specific ways. In fact, the number of possible connections among the brain's cells is truly astronomical—by some estimates, there are more possible connections among brain cells than there are atoms in the universe (Thompson, 1993)!

Not surprisingly, such complexity leads to many opportunities for the functioning of the brain to go awry. The brain is the organ of thinking, feeling, and behavior, and thus it must play a key role in psychopathology. In the following sections, we discuss the brain so that you can begin to understand the neurological aspects of specific psychological disorders that we consider later in the book. We start with the big picture by considering the overall structure of the brain and its organization into large systems. Then we turn to increasingly more detailed components, considering how individual brain cells interact within these systems.

A Quick Tour of the Nervous System

Psychopathology involves deficits in how a person thinks, feels, and behaves. The brain, of course, is ultimately responsible for all of these functions. Let's briefly consider how different parts of the brain contribute to cognitive and emotional capacities when the brain is structured and functions normally. In later chapters, when we need to know more to understand a specific psychological disorder, we'll look more closely at specific parts of the brain and how they can malfunction.

The Central Nervous System and the Peripheral Nervous System

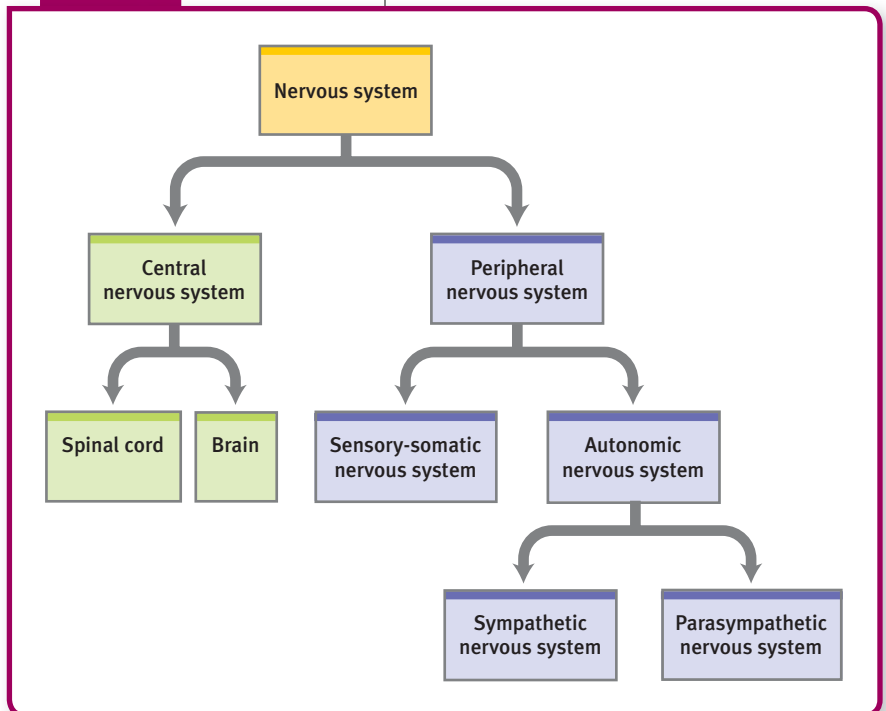

The central nervous system (CNS) has two parts: the brain and the spinal cord. The CNS is the seat of memory and consciousness, as well as perception and voluntary action (Smith & Kosslyn, 2006). However, the CNS is not the only neurological foundation of our internal lives. The peripheral nervous system (PNS) also plays an important role and is of particular interest in the study of psychopathology.

The Autonomic Nervous System

Like the CNS, the PNS is divided into two parts, in this case the sensory-somatic nervous system and the autonomic nervous system (see Figure 2.1). The *sensory-somatic nervous system* is involved in connecting the brain to the world, via both the senses (inputs) and the muscles (outputs). The *autonomic nervous system* (ANS) is probably of greater relevance to psychopathology, in part because it plays a key role in how we respond to stress (as we'll discuss shortly). The ANS controls many involuntary functions, such as those of the heart, digestive tract, and blood vessels (Goldstein, 2000; Hugdahl, 2001). The ANS itself has two major components: the sympathetic nervous system and the parasympathetic nervous system. The *sympathetic nervous system* revs you up so that you can respond to an emergency: It speeds up the heart (providing more blood and oxygen to the limbs) and dilates the pupils of the eyes (making you more sensitive to light). The sympathetic system also slows down functions that are not essential in an emergency, such as those involved in digestion. The sum result of the sympathetic nervous system's being activated is called the *fight-or-flight response*, (or the *stress response*, because it occurs when people experience stress).

As part of the fight-or-flight response, the *hypothalamic-pituitary-adrenal axis* (HPA axis) manages the production of the hormone cortisol, which readies the muscles for physical exertion by helping the body release fuel more effectively. Under chronic stress, a person's level of cortisol often doesn't

Figure 2.1

2.1 The Nervous System The autonomic nervous system (ANS) is part of the peripheral nervous system (PNS), and malfunctioning of the ANS can produce abnormal responses to stress.

return to baseline. The HPA axis and cortisol levels are involved in depression and stress-related psychological disorders such as *posttraumatic stress disorder (PTSD)*, an anxiety disorder that can arise after a person experiences a traumatic event.

The other part of the ANS is the *parasympathetic nervous system*, which settles you down after a crisis is over: The parasympathetic nervous system slows the heart, contracts the pupils, and also increases the activity of the digestive tract. The parasympathetic system typically counteracts the effects of the sympathetic nervous system, and psychopathology may arise if it fails to do so effectively. In fact, dysfunctional activity in the parasympathetic nervous system has been associated with various psychological problems, such as anxiety disorders, disruptive behavior, and hostility (Pine et al., 1998).

Figure 2.2

2.2 ▸ The Lobes of the Brain

The Four Brain Lobes

Let's now focus on one part of the CNS, the brain. As shown in Figure 2.2, the brain has four major lobes: occipital lobe, parietal lobe, temporal lobe, and frontal lobe. The brain is divided into two hemispheres (or half-spheres), left and right, and each hemisphere has all four lobes (although they do not have identical functions in the two hemispheres). Let's start with the back of the brain. When the eyes are stimulated by light, they send neural impulses into the brain; the first area to process this information in detail is the *occipital lobe*, which is at the very back of the brain. This lobe is entirely dedicated to the function of vision.

Two major neural pathways lead forward from the occipital lobes. One extends up into the *parietal lobe*, at the top, back of the brain. This lobe processes spatial information, such as the relative location of objects. The parietal lobe also has other functions, including a role in self-awareness. The second neural pathway from the occipital lobe leads down to the *temporal lobe* (so named because it lies under the temple), which stores visual memories, processes auditory information, and decodes the meaning of speech; the temporal lobe also contributes to conscious experience. Abnormal functioning in the temporal lobe can produce intense emotions, such as elation when a person is manic (Gyulai et al., 1997), and is associated with auditory hallucinations (Plaze et al., 2006).

Both the parietal lobe and the temporal lobe send information to the *frontal lobe*, which is located right behind the forehead. The frontal lobe plays crucial roles in feeling emotions and using emotional responses in decision making, as well as in thinking and problem solving more generally; it is also involved in programming actions and controlling body movements. Because these functions are so important to the vital activities of planning and reasoning, the frontal lobe is sometimes referred to as the seat of *executive functioning*; its role is much like that of the head of a successful company—an executive—who plans the company's future and formulates responses to obstacles that arise. Abnormalities in the frontal lobe, and in executive functioning, are associated with *schizophrenia*, a psychological disorder characterized by profoundly unusual and impaired behavior, expression of emotion, and mental processing (Bellgrove et al., 2006; Morey et al., 2005).

The Cortex and Beneath the Cortex

The **cerebral cortex** is the outer layer of cells on the surface of the brain; it contains the majority of the brain's **neurons**, the cells that process information related to our physical, mental, and emotional functioning. Most of the brain functions just described are carried out primarily in the cortex of the corresponding lobes. But many important brain functions are carried out in *subcortical areas*, beneath the cortex, as shown in Figure 2.3.

Cerebral cortex

The outer layer of cells on the surface of the brain.

Neurons

Brain cells that process information related to physical, mental, and emotional functioning.

Figure 2.3**2.3 ▶ Key Subcortical Brain Areas**

The *limbic system* plays a key role in emotions; among its most important components are the hypothalamus, the hippocampus, and the amygdala:

- The *hypothalamus* governs bodily functions associated with eating, drinking, and controlling temperature, and it plays a key role in many aspects of our emotions and in our experience of pleasure (Swaab, 2003).
- The *amygdala* is central to producing and perceiving strong emotions, especially fear (LeDoux, 2000).
- The *hippocampus* works to store new information in memory of the sort that later can be voluntarily recalled; (Squire, 2002).

In addition to components of the limbic system, other important subcortical areas are the thalamus, the nucleus accumbens, the basal ganglia, and the cerebellum:

- The *thalamus* is critical for controlling sleep and maintaining attention (and parts of it are closely involved with the limbic system; Lambert & Kinsley, 2005). Some people with schizophrenia have abnormalities in the structure and function of the thalamus, a finding that is consistent with their difficulties in focusing attention (Andreasen et al., 1994; Andrews et al., 2006).
- The *nucleus accumbens* plays a major role in registering reward and learning from experience (Breiter & Rosen, 1999). The functioning of the nucleus accumbens is involved in substance abuse (Leone, Pocock, & Wise, 1991).
- The *basal ganglia* are involved in automatic responses. Some psychological disorders disrupt the basal ganglia and can cause repetitive thoughts or behavior. For example, the basal ganglia operate abnormally in people who have *obsessive-compulsive disorder*, which is characterized by preoccupying thoughts and repetitive behaviors that the person feels compelled to do (Rauch et al., 2006).
- The *cerebellum* helps to manage physical coordination, attention, and many automatic motions (Ivry et al., 2002).

Both physical abnormalities and abnormal levels of activity in these subcortical brain areas can contribute to psychological disorders.

Neurons

Now that you know the essential functions that different parts of the brain perform, it's time to discuss *how* these functions occur. All brain activity depends on neurons, and malfunctions at the neuronal level often contribute to psychological disorders (Lambert & Kinsley, 2005). The brain contains numerous types of neurons, which have different functions, shapes, and sizes. Most neurons interact with other neurons. In some cases, neurons *activate*, or act to “turn on,” other neurons; in other cases, neurons *inhibit*, or act to “turn off,” other neurons. We can classify neurons into three main types:

- *sensory neurons* receive input from the sense organs (eyes, ears, and so on);
- *motor neurons* carry output that stimulates muscles and glands; and
- *interneurons* lie between other neurons—sensory neurons, motor neurons, and/or other interneurons—and make up most of the neurons in the brain.

Sets of connected neurons that work together to accomplish a basic process, such as making you recoil when you touch a hot stove, are called **brain circuits**; sets of brain circuits are organized into **brain systems**, which often can involve most of an entire lobe—or even large portions of several lobes. Many forms of psychopathology arise because specific brain circuits are not working properly, either alone or as part of a larger brain system. To understand brain circuits, consider an analogy to a row of dominoes: When one domino falls, it causes the next in line to fall, and so on, down the line. Similarly, when a neuron within a brain circuit is activated, it in turn activates sequences of other neurons. However, unlike a domino in a row, the average neuron is connected to about 10,000 other neurons—and thus a complex pattern of spreading activity occurs when a brain circuit is activated. For each input, a brain system produces a specific output—for instance, an interpretation of the input, an association to it, or a response based on it. Ultimately, it is the pattern of activated neurons that is triggered—by a sight, smell, thought, memory, or other event—that gives rise to our cognitive and emotional lives. A pattern of neurons firing makes us desire that third piece of chocolate cake or causes us to recoil when a spider saunters out from behind it. Brain systems allow us to think, feel, and behave.

Psychopathology can arise when neurons fail to communicate appropriately, leading brain circuits to produce incorrect outputs. For example, people with schizophrenia appear to have abnormal circuitry in key parts of their frontal lobes (Pantelis et al., 2003; Vidal et al., 2006). To understand such problems—and possible treatments for them—you need to know something about the structure and function of the neuron and its methods of communication.

The Cell Body

To see how neurons can fail to communicate appropriately, we must take a closer look at their anatomy. Figure 2.4 shows that a neuron has three parts: a receiving end, a sending end, and a middle part, called the *cell body*. Neurons, like all human cells, have a *nucleus*, which regulates all of the functions of the neuron, and a *cell membrane*, which forms an outer covering. When a neuron receives a sufficient amount of excitatory input, very small holes in the cell membrane—called *channels*—open, and the neuron's internal balance of chemicals will change to the point where the neuron fires. It is this firing that sends information to other neurons (Lambert & Kinsley, 2005).

Each neuron registers the sum total of inputs, both those that try to stimulate it to fire and those that try to inhibit it from firing. The neuron, then, balances the two sorts of inputs against each other and only fires if the stimulating influences substantially outweigh the inhibiting ones (Kandel, Schwartz, & Jessell, 2007). To understand how firing occurs, we need to look at the two other major parts of the neuron: the axon and the dendrites.

Brain circuits

Sets of connected neurons that work together to accomplish a basic process.

Brain systems

Sets of brain circuits that work together to accomplish a complex function.

The Axon

The *axon* is the part of the neuron that sends signals when a neuron fires. The axon is a long, threadlike structure covered by a layer of fatty material, known as the myelin sheath, that insulates it electrically. Though a neuron has only a single axon, it often branches extensively, allowing signals to be sent simultaneously to many other neurons (Shepherd, 1999). When a neuron has been stimulated to the point that it fires, a wave of chemical activity moves from the cell body down the axon very quickly. This wave is called an **action potential**. When the action potential reaches the end of the axon, it typically causes chemicals to be released. These chemicals are stored in structures called *terminal buttons*, and they affect other neurons, muscles, or glands.

If stimulation does not cause a neuron to fire when it should, the circuit of which it is a part will not function correctly—and psychopathology may result. Let's consider why a neuron might not fire when stimulated appropriately.

The Dendrites

Neurons fire when they are appropriately stimulated. But how are they stimulated? Two ways: First, through *dendrites*, which receive signals from other neurons. These dendrites are highly branched, so a single neuron can receive many different signals at the same time. Received signals move along the dendrites to the cell body (Kandel, Schwartz, & Jessell, 2007). Second, in some cases, neurons receive inputs directly on their cell bodies. Such inputs are produced not only by other neurons, but also by *glial cells*. Glial cells are involved in the “care and feeding” of neurons, and act as a kind of support system (in fact, *glial* means “glue” in Greek; Lambert & Kinsley, 2005). The brain has about ten times as many glial cells as neurons, which implies that glial cells are important. In fact, researchers have learned that glial cells do much more than provide support services; they can directly stimulate neurons, and play a role in modulating input from other neurons (Parpura & Haydon, 2000).

Given the roles of neurons and glial cells in brain function, it is not surprising that researchers have found that at least some patients with psychological disorders (specifically, the sorts of mood disorders we consider in Chapter 6) have lost both types of cells. One possible reason for such deficits may be that stress early in childhood (and even to the mother, prior to a child's birth) can disrupt the development of both neurons and glial cells (Zorumski, 2005).

Chemical Signals

The way neurons communicate is crucial for understanding psychopathology. In many cases, psychological disorders involve faulty signaling among neurons, and effective medications operate by altering the ways in which signals are produced or processed (Kelsey, Newport, & Nemeroff, 2006). Subsequent chapters of this book will describe how particular signaling problems contribute to some psychological disorders and how certain medications compensate for such problems. To understand these problems with chemical signaling, we now need to consider the following: what

Figure 2.4

2.4 ▶ The Neuron

Action potential

The wave of chemical activity that moves from the cell body down the axon when a neuron fires.

Figure 2.5**2.5 The Synapse**

happens at the synapse, what neurotransmitters and neuromodulators do, the nature of receptors, and what can go wrong with chemical communication among neurons.

The Synapse

When a neuron fires and chemicals are released at the terminal button, those chemicals usually contact another neuron at a **synapse**, which is the place where the tip of the axon of one neuron nestles against another neuron (usually at a dendrite) and sends signals to it. Most of the time, the sending neuron is not physically connected to the receiving neuron, though. Instead, the chemicals carry the signal across a gap, called the **synaptic cleft**, shown in Figure 2.5. Events at the synapses can go awry, which can underlie a variety of types of psychopathology.

Neurotransmitters and Neuromodulators

The chemicals that are released at the terminal buttons are called **neurotransmitters**. Neurotransmitters can be distinguished from **neuromodulators**, which are chemicals that modulate (alter) the way neurotransmitters affect the receiving neuron. Some neuromodulators affect the function of neurotransmitters by altering events at the synapse, for instance, by slowing down the rate at which molecules of a neurotransmitter are removed from the synaptic cleft after having been released. However, researchers have discovered that some chemicals that act as neurotransmitters can also act as neuromodulators in certain circumstances, and vice versa (Dowling, 1992). Thus, what originally seemed to be a sharp distinction, between neurotransmitters and neuromodulators, has become blurred. Researchers now often use the term *neurotransmitter* broadly,

to include both sorts of substances, or they refer to both sorts as *neurotransmitter substances*.

It is worth looking briefly at the major neurotransmitter substances that play roles in psychological disorders. However, keep in mind that no neurotransmitter substance works in isolation and that no psychological disorder can be traced solely to the function of a single neurotransmitter substance. Nevertheless, imbalances in some of these substances have been linked, to some extent, with certain psychological disorders.

Dopamine is involved in reward and motivation, and it also plays roles in executive functions in the frontal lobe, including those that orchestrate body movements. Too little dopamine is thought to play a role in attention-deficit/hyperactivity disorder and depression (Bressan & Crippa, 2005). Too much dopamine is thought to play a role in inappropriate aggression and schizophrenia (Buchsbaum et al., 2006).

Serotonin is largely an inhibitory neurotransmitter involved in mood and sleep, as well as motivation. Too little serotonin may play a role in depression and obsessive-compulsive disorder (Mundo et al., 2000); too much of it may reduce a person's motivation.

Acetylcholine plays a particularly important role in the hippocampus, where it is involved in the processes that store new information in memory. It is also found in the ANS and is involved in the fight-or-flight response (which plays a role in panic responses, as we discuss in Chapter 7). Too little acetylcholine is apparently involved in the production of delusions (Rao & Lyketsos, 1998), and too much can contribute to spasms, tremors, and convulsions (Eger et al., 2002).

Synapse

The place where the tip of the axon of one neuron sends signals to another neuron.

Neurotransmitters

Chemicals that are released at the terminal buttons and cross the synaptic cleft.

Neuromodulators

Chemicals that modulate (alter) the way neurotransmitters affect the receiving neuron. Some chemicals that act as neurotransmitters can also act as neuromodulators in certain circumstances, and vice versa.

Adrenaline (also called *epinephrine*) plays a role in attention and in the fight-or-flight response (Nemeroff, 1998). Too little of this substance in the brain contributes to depression, and too much can lead to over-arousal and feelings of apprehension or dread.

Noradrenaline (also called *norepinephrine*) also plays a role in attention and the fight-or-flight response. Too little contributes to distractibility, fatigue, and depression (Meana et al., 1992); too much has been implicated in schizophrenia and anxiety disorders (Nutt & Lawson, 1992).

Glutamate is a fast-acting excitatory neurotransmitter found throughout the brain. It plays a role in registering pain and in the formation of new memories. Too much glutamate is involved in various disorders, including substance abuse (Kalivas & Volkow, 2005), and too little is associated with other disorders, notably schizophrenia (Muller & Schwarz, 2006).

Gamma-amino butyric acid (GABA) is a common inhibitory substance. Too little of it is associated with anxiety and (possibly) panic disorder (Goddard et al., 2001); too much appears to undermine motivation.

Endogenous cannabinoids are involved in emotion, attention, memory, appetite, and the control of movements (Wilson & Nicoll, 2001). Too little of these substances is associated with chronic pain; an excess is associated with eating disorders, memory impairment, attention difficulties, and possibly schizophrenia (Giuffrida et al., 2004).

You may have noticed that these descriptions of what the chemical substances do are fairly general. There's a reason for that: The effects of these substances depend only in part on their nature; the effects also depend on the nature of the receiving neurons. Thus, we must next look more closely at what's on the receiving end of these chemical substances.

Chemical Receptors

A neuron receives chemical signals at its **receptors**, specialized sites that respond only to specific molecules (see Figure 2.5). Located on the dendrites or on the cell body, receptors work like locks into which only certain kinds of keys will fit (Kelsey, Newport, & Nemeroff, 2006; Lambert & Kinsley, 2005). However, instead of literally locking or unlocking the corresponding receptors, the neurotransmitter molecules *bind* to the receptors and affect them either by exciting them (making the receiving neuron more likely to fire) or by inhibiting them (making the receiving neuron less likely to fire). We noted earlier that a sending neuron can make a receiving neuron more or less likely to fire, and now we see how these effects occur: The sending neuron releases specific neurotransmitters.

Although each neuron produces only a small number of neurotransmitters, those chemicals often bind to many different types of receptors (Kelsey, Newport, & Nemeroff, 2006). When a neuron fires, the effect of this event depends on how its neurotransmitters bind to receptors on the receiving neuron. The same chemical can have different effects on a neuron depending on which kind of receptor it binds to. For example, dopamine acts as a neurotransmitter in the subcortical reward circuits of the nucleus accumbens. In fact, most abused substances directly or indirectly affect dopamine activity, which in turn activates those reward circuits; this pleasurable experience leads many individuals to want to use the abused substance again to reexperience that state (Tomkins & Sellers, 2001). However, dopamine also acts as a neuromodulator in the frontal lobes (Robbins, 2000), and disruption of its role in executive functions may be critical in schizophrenia.

Abnormal Communications Among Neurons

How can communications among neurons at the synaptic cleft go awry, and thereby lead to psychological disorders? Scientists point to at least three ways in which such communications can be disrupted: First, neurons might have too many or too few dendrites or receptors, making the neurons more or less sensitive, respectively, to even normal amounts of neurotransmitter substances in the synaptic

Receptors

Specialized sites on dendrites and cell bodies that respond only to specific molecules.

cleft (Meana, Barturen, & Garcia-Sevilla, 1992). If the neurons in an inhibitory circuit are abnormal in this way, the brain may have difficulty dampening down repetitive thoughts or behaviors—as occurs in certain disorders we will discuss later in this book.

Second, the sending neurons might produce too much or too little of a neurotransmitter substance. Third, the events after a neuron fires may go awry (Kelsey, Newport, & Nemeroff, 2006). In particular, when a neuron fires and sends neurotransmitter chemicals to another neuron, not all of these molecules bind to receptors. Rather, some of the molecules linger in the synaptic cleft and need to be removed. Special chemical processes operate to **reuptake** these leftover neurotransmitters, moving them back into the sending neuron. Sometimes reuptake does not operate correctly, which may contribute to a psychological disorder. For example, neurons might not reabsorb enough of the molecules from the synaptic cleft, which results in chronically high levels of neurotransmitter (Kandel, Schwartz, & Jessell, 2007; Kelsey, Newport, & Nemeroff, 2006). You might think that this would mean that the receiving neuron is habitually stimulated too much, but in fact the neuron alters its sensitivity to the neurotransmitter so that abnormally high amounts must be produced by the sending neuron to be registered. And if abnormally high amounts are not in fact produced, the functional results are the same as if not enough neurotransmitter were being produced. As we saw earlier, many psychological disorders are associated with too little of a specific neurotransmitter substance.

Hormones and the Endocrine System

Not all neurotransmitter substances are released across synapses. **Hormones** are neurotransmitter substances that are released directly into the bloodstream and often function primarily as neuromodulators; their effect is more general and more widespread than that of neurotransmitters released into synapses (Kelsey, Newport, & Nemeroff, 2006). Like other neurotransmitter substances, hormones can activate or modulate the activity of neurons. For example, some hormones play a key role in helping animals respond to stressful situations by altering the functioning of the ANS (Kandel, Schwartz, & Jessell, 2007). However, traumatic events can disrupt this often-helpful mechanism and contribute to psychological disorders such as depression (Claes, 2004).

Hormones are produced by glands in the *endocrine system*, which secretes substances into the bloodstream. Hormones affect various organs throughout the body. As we noted when we discussed the HPA axis, *cortisol* is a particularly important hormone, which helps the body to cope with challenges by making more resources available (by breaking down fats and proteins and converting them to sugar); cortisol is produced by the adrenal glands (which are located right above the kidneys), and abnormal amounts of cortisol have been linked to anxiety and depression. Some substances, such as adrenaline, function as neurotransmitters in the brain and also as hormones in the body (Lambert & Kinsley, 2005). As noted earlier, we cannot link a psychological disorder solely to the relative amounts of a given transmitter substance: We must also take into account the nature of the neurons (and the circuits in which they participate) that have receptors for that substance.

The Genetics of Psychopathology

Researchers knew about the inheritance of traits long before the discovery of DNA (deoxyribonucleic acid, the long molecule that contains many thousands of genes). Everyone knows that people “take after” their parents in some ways, and genes are responsible for this phenomenon. Genes affect not only physical traits but also the brain and, through the brain, thinking, feeling, and behavior; moreover, genes affect how vulnerable people are to particular psychological disorders (Plomin et al., 1997, 2003).

The study of genetics dates back to Gregor Mendel, an Augustinian monk who lived and worked in what is now the Czech Republic. In 1866, he published a paper

Reuptake

The process of moving leftover neurotransmitter molecules in the synapse back into the sending neuron.

Hormones

Neurotransmitter substances that are released directly into the bloodstream and often function primarily as neuromodulators.

that formulated the core ideas of **Mendelian inheritance**, or the transmission of traits by separate elements (which turned out to be genes). The two most important aspects of Mendelian inheritance are that:

1. Each parent transmits a distinct “element” to its offspring, which specifies each trait.
2. One element may dominate the other in the expression (or nonexpression) of the trait in the offspring. The element that is not *dominant* is called *recessive*. The offspring will show the effect of the recessive element only if neither parent transmits the dominant element, leaving the offspring with two copies of the recessive element, one from each parent.

In the middle of the 20th century, James Watson and Francis Crick famously identified the “elements” that Mendel hypothesized as **genes**, which correspond to segments of DNA that control the production of particular proteins and other substances (see Figure 2.6). For many traits, gene variants—referred to as *alleles*—determine how the trait is manifested. The sum of an organism’s genes is called its **genotype**. In contrast, the sum of its observable traits is called its **phenotype**, and many aspects of the phenotype are determined by how the genotype is expressed in a particular environment.

At one time differences in eye color were used as an example of the effects of having different alleles, with brown being dominant and blue recessive. This example has mostly been dropped from textbooks for a simple reason: Eyes come in a huge range of colors, not just two (if you need to be convinced of this, check out the eye colors of your friends). Thus, Mendelian inheritance doesn’t really explain differences in eye color. In fact, most traits do not arise from simple combinations of dominant and recessive genes. Rather, for most traits, many genes work together to cause particular effects. Such sets of genes give rise to traits, such as height, that are expressed along a continuum, and the joint actions of these genes produce **complex inheritance** (Plomin et al., 1997). Traits that arise from complex inheritance cannot be linked to a few distinct genes, but rather emerge from the interactions among the effects of numerous genes. Almost all psychological disorders that have a genetic component, such as schizophrenia and depression, arise in part through complex inheritance (Faraone, Tsuang, & Tsuang, 2001; Plomin et al., 2003).

Behavioral Genetics

Studies that investigate the contributions of genes to mental illness rely on the methods of **behavioral genetics**, which is the field that investigates the degree to which the variability of characteristics in a population arises from genetic versus environmental factors (Plomin et al., 2003). With regard to psychopathology, behavioral geneticists consider these questions: What is the role of genetics in causing a particular mental disorder? What is the role of the environment? And what is the role of interactions between genes and the environment?

Throughout this book, we discuss the relative contributions of genes and the environment to the development of specific mental disorders. We must always keep in mind, however, that any conclusions about the relative contributions of the two influences are always tied to the specific environment in which the contributions are measured. To see why, consider the following example (based on Lewontin, 1976). Imagine three situations in which we plant two apple trees of the same variety, one of which has genes for large apples and one of which has genes for small apples.

Figure 2.6

2.6 DNA

Mendelian inheritance

The transmission of traits by separate elements (genes).

Genes

Segments of DNA that control the production of particular proteins and other substances.

Genotype

The sum of an organism’s genes.

Phenotype

The sum of an organism’s observable traits.

Complex inheritance

The transmission of traits that are expressed along a continuum by the interaction of sets of genes.

Behavioral genetics

The field that investigates the degree to which the variability of characteristics in a population arises from genetic versus environmental factors.

David Young-Wolff/PhotoEdit

In Western countries, genes account for about .32 of the variation in generalized anxiety disorder; in other words, in this context, this disorder is about 32% heritable. This does not mean that the likelihood that a given person living in a Western country will develop generalized anxiety disorder is determined 32% by the genes and 68% by the environment; it means that about a third of the variation across the whole population of that environment (Western countries) is determined by genetics.

Heritability

An estimate of how much of the variation in a characteristic within a population (in a specific environment) can be attributed to genetics.

In the first case, we keep the environment the same for the two trees. Unfortunately for them, however, it is not a very friendly environment: The soil is bad, the trees are in the shade, and there isn't much water. Both trees produce small apples. In this case, the environment overshadows the genetic influence for large apples.

In the second case, the trees are luckier. We keep the environment the same for the two trees, but the soil is rich, the trees are in the sun, and they receive plenty of water. What happens? The tree with genes for large apples produces larger apples than the tree with genes for small apples.

In the third case, the tree with genes for large apples is planted in the impoverished environment, and the tree with genes for small apples is planted in the favorable environment. Now, the tree that has genes for small apples might produce bigger apples than the tree with genes for large apples because the environmental conditions have favored the former and acted against the latter.

As this example makes clear, for trees and other organisms—including people—the influence of genes must be described in relation to the environment in which they function. In other words, genes and environment interact through *feedback loops*—and in fact, that's why the phenotype is described as the product of genes in a specific environment. The same genes can have different effects in different environments. A research finding of a certain degree of genetic influence on a disorder in one environment does not necessarily have any relationship to the degree of genetic influence on the disorder in other environments. For example, the fact that genes can predispose an individual to alcoholism has different effects in the alcohol-embracing culture of France and the alcohol-shunning culture of Pakistan.

Heritability

Behavioral genetics characterizes the relative influence of genetic factors in terms of the heritability of a characteristic. **Heritability** is an estimate of how much of the variation in that characteristic within a population (in a specific environment) can be attributed to genetics. For example, the heritability of *generalized anxiety disorder* (which is characterized by anxiety that is not associated with a particular situation or object, as we will discuss in detail in Chapter 7) is about .32 in citizens of Western countries (Hetteman, Neale, & Kendler, 2001). This means that about a third of the variation in generalized anxiety disorder in this population is genetically determined. Note that this estimate of .32 does *not* mean that any particular person's likelihood of developing the disorder is determined 32% by genes and 68% by environment.

How do researchers estimate the heritability of a given psychological disorder? There is no sure-fire research method, because many variables can affect the results. For example, if researchers find a similar prevalence of a mental disorder in children and their parents, can they assume genetic inheritance? Not necessarily; they would have to rule out any effects of the environment that might be operating. As an extreme example, suppose that for generations, the members of a given family always prepare their meals in lead pots, and hence each generation of children *becomes* mentally retarded because of lead poisoning. This mental retardation is not a result of genetics. Furthermore, it is difficult to assess "the environment" for a given person. The environment must be understood not in objective terms, but rather in terms of how situations and events are perceived and understood. For instance, for siblings in a given family, does having divorced parents constitute the same environment? Not exactly: A child's age at the time of parents' divorce can influence how the child experiences the divorce. A preschooler might believe he or she somehow caused the divorce, whereas an older child—who is more mature cognitively, emotionally, and socially—is less likely to make that inference (Allison & Furstenberg, 1989; Hoffman, 1991). Researchers can entirely avoid such age effects between siblings by studying twins.

Twin and Adoption Studies

Twin studies compare some characteristic, or set of characteristics, in two groups of twins, identical and fraternal. Identical twins have basically the same genetic makeup, because they began life as a single fertilized egg (or *zygote*) that then divided to become two embryos. Such twins are **monozygotic** (*mono-* means “one”). However, even identical twins do not have absolutely identical sets of genes: They may differ in how often particular genes are repeated, which in turn has effects on how the genes operate (Bruder et al., 2008). Fraternal twins begin life as different fertilized eggs, and so are **dizygotic** (*di-* means “two”). Fraternal twins are like any other nonidentical siblings in terms of their genetic similarity: They have about 50% overlap in the genes that vary among humans. When researchers compare the characteristics of monozygotic twins and dizygotic twins, controlling as much as possible for the environment, they can attempt to draw conclusions about the relative contribution of genes to those characteristics in that environment. For instance, such studies have suggested that schizophrenia is about 50% heritable (Gottesman, 1991). However, we must be cautious about such estimates: Not only can identical twins have slightly different sets of genes, but they begin to have different experiences before birth—in fact, one twin is usually heavier and larger at birth, because of differences in the amounts of nutrients the two fetuses receive in the womb (Cheung, Bocking, & Dasilva, 1995; Hollier, McIntire, & Leveno, 1999).

Sometimes researchers try to discover the roles of genes and the environment in mental disorders by conducting *adoption studies*: They study twins who were separated at birth and raised in different homes, then compare them to twins who were raised in the same home. In addition, researchers also study unrelated children who were adopted and raised together, then compare them to unrelated children who were reared in different homes. But even in adoption studies, it's not easy to disentangle the effects of genes and the environment. The reason is that genetic differences influence the environment—a relationship that is characterized by the *reciprocal gene–environment model*. For instance, suppose that a pair of twins has genes that lead them to be high-strung and very active. Even if these twins are raised apart in different environments, their parents may react similarly to them—trying to keep them calm and out of trouble, which might mean that they wouldn't be taken on family outings as often as children who were less of a handful. Or perhaps their genes lead the twins to be bright and ask a lot of questions. In this case, both sets of adoptive parents might take them to museums and talk to them a lot. The point is that even in different adopted households, genes can influence how twins are treated and what they experience. Thus, although twin and adoption studies can be fascinating, their findings must be interpreted cautiously.

The problems with twin and adoption studies have led many researchers to take advantage of recent technological advances in genetics: It is now possible to assess, inexpensively and quickly (for many genes), whether a particular person has a specific allele of a gene (Schena et al., 1995). Researchers have used such techniques to attempt to find associations between the presence or absence of specific alleles and psychological disorders. For example, Rasmussen and colleagues (2006) found that people who develop schizophrenia relatively late in life tend to have one particular allele of a certain gene, which may act either to make them susceptible to late-developing schizophrenia or to delay the onset of the disease in them until later in life. However, such research has proven difficult because many genes contribute to most disorders, and they interact in complex ways. Thus, any one gene is likely to have a relatively small role in most psychological disorders.

Paul Whitehill/Photo Edit

It is not easy to sort out the effects of genetics from those of the environment by studying identical twins. Each twin has unique experiences even before he or she is born: One twin may get less nutrients or be exposed to more toxins while in the mother's womb; that is, there can be different environments for the twins even before birth.

Monozygotic twins

Twins who have basically the same genetic makeup (although it may differ in how often specific genes are repeated) because they began life as a single fertilized egg (*zygote*), which then divided into two embryos; also referred to as *identical twins*.

Dizygotic twins

Twins who developed from two fertilized eggs and so have the same overlap in genes (50%) as do siblings not conceived at the same time; also referred to as *fraternal twins*.

FEEDBACK LOOPS IN ACTION: The Genes and the Environment

We've seen how genes can affect the environment, but—to the surprise of many—the genes themselves are also affected by the environment, including psychological and social factors. We consider the feedback loop between the environment and the genes in the following two sections.

The Environment Affects the Genes

Many people seem to think of genes as instructions for building the brain and the body, guiding the construction process and then ceasing to function. For most genes, this is not so. Even in adulthood, a person's genes are being regulated by the environment (Hyman & Nestler, 1993). Consider a simple example: Did you ever try to learn to play piano? If you did, your fingers were probably sore after even a half-hour of practice. But if you stuck with it, you could play for longer and longer periods with no discomfort. What happened? Your muscles got stronger—but how? When you first began, the stress of using your fingers in new ways actually damaged the muscles (which is why they felt sore). Then, a series of chemical events inside the muscle cells of your fingers *turned on* genes in the nuclei of these cells. These genes directed the cells to produce more proteins, to build up the muscles, which made them stronger. If you stopped playing for a period of time, those genes would turn off, and the muscles would become weaker. Which is why your fingers might be sore when you first resumed playing after having taken a long break.

The point is that some genes are activated, or turned on, as a result of experience, of interacting with the world (Kandel, Schwartz, & Jessell, 2007). This is true of genes in the brain that produce neurotransmitters and that cause new synapses to form. In fact, when you learn, genes in your brain are turned on, which causes new connections among neurons to be formed. This is true even when you learn maladaptive behaviors, which can produce, among other problems, a *phobia*—an intense, irrational fear of an object or situation.

Moreover, genetic factors can contribute to a neurological vulnerability for a psychological disorder. For example, genetic factors can lead a person to be prone to learning maladaptive behaviors.

However, genes are not destiny. More often than not, having specific genes does not determine behavior, but rather predisposes one to be affected by the environment in certain ways. That is, genes can predispose a person for a specific disorder, but those genes may have that effect only when triggered by psychological or social factors.

The Genes Affect the Environment

We've just seen how the environment affects the genes, and we've already noted that the reverse also occurs. Let's now look in more detail at ways in which the genes affect the environment. Many researchers (Plomin et al., 1997; Scarr & McCartney, 1983) distinguish three ways in which genes affect the environment—passive interaction, evocative interaction, and active interaction:

1. *Passive interaction.* The parents' genes affect the child's environment—and the child passively receives these influences. For instance, some parents avoid large social groups because they are shy, which is in part a result of their genes; this means that their child does not have many social experiences. The child may not have inherited the parents' shy temperament, but the parents' genes nonetheless act through the environment to affect the child.
2. *Evocative interaction* (also called *reactive interaction*). A person's inherited traits encourage other people to behave in particular ways, and hence the person's social environment will be affected by his or her genes. For example, if you are very tall and heavy-set, others may respond to you somewhat cautiously—in a way they would not if you were short and frail. Similarly, others may approach or avoid you (fairly or not!) in response to your temperament (e.g., shy, calm, high-strung); any specific temperament will appeal to some and not to others. Thus, even your circle

of friends will be somewhat determined by your genes, and those friends will then affect you in certain ways depending on their own characteristics.

3. *Active interaction.* Each of us actively seeks out some environments and avoids others, and our genes influence which environments feel most comfortable to us. For example, a person who is sensitive to environmental stimulation might prefer spending a quiet evening at home curled up with a good book instead of going to a loud, crowded party at a friend's house.

The interactions between genes and the environment involve all of the factors considered by the neuropsychosocial approach, and hence create complex feedback loops. Once the environment (including social factors, such as one's choice of friends) has been influenced by genes, the environment affects the genes (as well as one's knowledge, beliefs, attitudes, and so on).

Again, the import of these observations for psychological disorders is clear. Genes can make a person at risk for a particular psychological disorder, but other factors—psychological and social—can influence the expression of the genes. And the specific psychological and social factors that affect a person arise, in part, from that person's genes (which affect, for example, aspects of his or her appearance). Thus, even though genes may make some people vulnerable to specific kinds of mental illness, the path from genes to illness is neither straight nor inevitable.

Key Concepts and Facts About Neurological Factors in Psychological Disorders

- The nervous system has two major parts: the central nervous system (CNS), which is composed of the brain and spinal cord, and the peripheral nervous system (PNS), which is composed of the sensory-somatic nervous system and the autonomic nervous system (ANS).
- The ANS controls many involuntary functions, such as those of the heart, blood vessels, and digestive tract. The ANS has two major components:
 - The sympathetic nervous system, which produces more adaptive bodily functioning in an emergency with the fight-or-flight response. As part of this response, the hypothalamic-pituitary-adrenal axis (HPA axis) manages the production of cortisol, which helps the muscles prepare for physical exertion. The HPA axis and high levels of cortisol are involved in depression and stress-related psychological disorders.
 - The parasympathetic nervous system, which typically brings the body back to its normal state after a fight-or-flight response. The parasympathetic system typically counteracts the effects of the sympathetic nervous system, and psychopathology may arise if it fails to do so effectively.
- The brain is divided into two hemispheres; the lobes of which (along with their key functions) are: occipital lobe (involved in vision), parietal lobe (involved in processing spatial information and self-awareness), temporal lobe (involved in processing auditory information, including speech, and memory), and frontal lobe (site of executive functioning).
- Subcortical (beneath the cortex) areas of importance (along with their key functions) are as follows:
 - The limbic system, which plays a key role in emotions and includes the hypothalamus (involved in controlling eating, drinking, temperature, and emotions), the amygdala (central to producing and perceiving strong emotions), and the hippocampus (involved in storing new information in memory);
 - The thalamus (involved in controlling sleep and maintaining attention);
 - The nucleus accumbens (involved in registering reward and learning from experience);
 - The basal ganglia (involved in automatic responses); and
 - The cerebellum (involved in physical coordination and automatic motions).
- There are three types of neurons: sensory neurons, motor neurons, and interneurons (most neurons are interneurons). Neurons communicate with each other to create patterns of activation in brain circuits, which in turn are organized into large brain systems; these systems may be disrupted in cases of psychopathology.
 - A neuron has a cell body, an axon that ends in terminal buttons, and dendrites that receive signals from other neurons. The neuron is covered by a cell membrane that has channels that open when the neuron fires.
 - When a neuron fires, neurotransmitters released from the terminal buttons travel across the synaptic cleft to receptors on the dendrite or cell body of another neuron. Neuromodulators may affect the functioning of neurotransmitters by altering events at the synapse.
- Neurotransmitter substances include dopamine (involved in reward, motivation, and executive functioning), serotonin (involved in mood, sleep, and motivation), acetylcholine (involved in memory and the fight-or-flight response), adrenaline and noradrenaline

continued on next page

(involved in attention and the fight-or-flight response), glutamate (involved in registering pain and the formation of new memories), GABA (involved in anxiety and motivation), and endogenous cannabinoids (involved in emotion, attention, memory, appetite, and the control of movements).

- Neurotransmitters can bind to different types of receptors; the type of receptor a neurotransmitter binds to determines its effect.
- Neuronal communication can go awry when (1) neurons have an abnormal number of dendrites or receptors, affecting sensitivity to neurotransmitters in the synaptic cleft; (2) sending neurons release abnormal amounts of neurotransmitter into the synapse; (3) reuptake of neurotransmitter molecules does not operate correctly.
- Hormones, produced by glands in the endocrine system, often function as neuromodulators; an important hormone related to some psychological disorders is cortisol.

- Genes can influence the development of psychopathology. Complex inheritance best explains the influence of genes on psychological disorders. Scientists who study behavioral genetics seek to determine the roles of genes, the environment, and their interactions in both normal and abnormal thoughts, feelings, and behaviors. Heritability is an estimate of how much of the variation of a characteristic across a population, *in a specific environment*, is determined by genes.
- Behavioral geneticists may use twin and adoption studies to determine the relative influences of genes and environment. Twins are either monozygotic or dizygotic. The environment can affect genes by influencing when—and which—genes are turned off and on. Genes can affect the environment in three ways: (1) passive interaction, (2) evocative interaction, and (3) active interaction.

Psychological Factors in Psychological Disorders

Both of the Beale women had idiosyncratic ideas and inclinations. For instance, Little Edie, in talking about World War II, expressed an unusual view about who should be soldiers and sent off to fight a war—people who are not physically healthy and hardy. With such people as soldiers, she claimed, the war would be over sooner (Maysles, 2006). In addition, Big Edie was known to command Little Edie to change her attire, repeatedly, up to 10 times each day (Maysles, 2006). Psychological factors, such as learning, can help to account for people's beliefs and behavior. Could aspects of Big Edie and Little Edie's views and lifestyle have been learned? And how might their emotions—such as Big Edie's fear of being alone or Little Edie's resentment of her mother's control—influence their thoughts and behavior? Let's examine the role that previous learning, mental processes and contents, and emotions can play in psychological disorders.

Behavior and Learning

As we saw in Chapter 1, psychological disorders involve distress, impaired functioning, and/or risk of harm. These three elements can be expressed in behaviors, such as occurs when people disrupt their daily lives in order to avoid feared stimuli or when they drink too much alcohol to cope with life's ups and downs. Many behaviors related to psychological disorders can be learned. As we shall see, some psychological disorders can be explained, at least partly, as a consequence of one of three types of learning: classical conditioning, operant conditioning, and observational learning.

Classical Conditioning

In a landmark study of an 11-month-old infant, known as “Little Albert,” behaviorists John B. Watson and Rosalie Rayner (1920) demonstrated how to produce a phobia. The researchers conditioned Little Albert to be afraid of white rats, using the basic procedure of Pavlovian conditioning (see Chapter 1), except in this case the reflexive behavior was related to fear rather than salivation. To do

Classical conditioning

A type of learning that occurs when two stimuli are paired so that a neutral stimulus becomes associated with another stimulus that elicits a reflexive behavior; also referred to as *Pavlovian conditioning*.

this, they made a very loud sound immediately after a white rat (which was used as the neutral stimulus) moved into the child's view; they repeated this procedure several times. Whenever Little Albert subsequently saw a white rat, he would cry or exhibit other signs of fear. The process that generated Little Albert's fear of white rats is called **classical conditioning**—a type of learning that occurs when two stimuli are paired so that a neutral stimulus becomes associated with another stimulus that elicits a reflexive behavior; classical conditioning is also referred to (less commonly) as Pavlovian conditioning. By experiencing pairings of the two stimuli (the white rat and the loud noise in the case of Little Albert), the person comes to respond to the neutral stimulus alone (the white rat) in the same way that he or she had responded to the stimulus that elicited the reflexive behavior (the loud noise).

How, specifically, does classical conditioning occur? Using the lingo of psychologists, the stimulus that reflexively elicits a behavior is called the **unconditioned stimulus (UCS)**, because it elicits the behavior without prior conditioning. In the case of Little Albert, the loud noise was the UCS, and the behavior it reflexively elicited was a startle response associated with fear. Such a reflexive behavior is called an **unconditioned response (UCR)**. The neutral stimulus that, when paired with the UCS, comes to elicit the reflexive behavior is called the **conditioned stimulus (CS)**. It is called the conditioned stimulus because its ability to elicit the response is *conditional* on its being paired with a UCS. In Little Albert's case, the CS was the white rat. The **conditioned response (CR)** is the response that comes to be elicited by the previously neutral stimulus (the CR is basically the same behavior as the UCR, but the behavior is elicited by the CS). In Little Albert's case, the CR was the startle response to the rat alone (and ensuing fear-related behaviors, such as crying and trying to avoid the rat). The process of classical conditioning is illustrated in Figure 2.7.

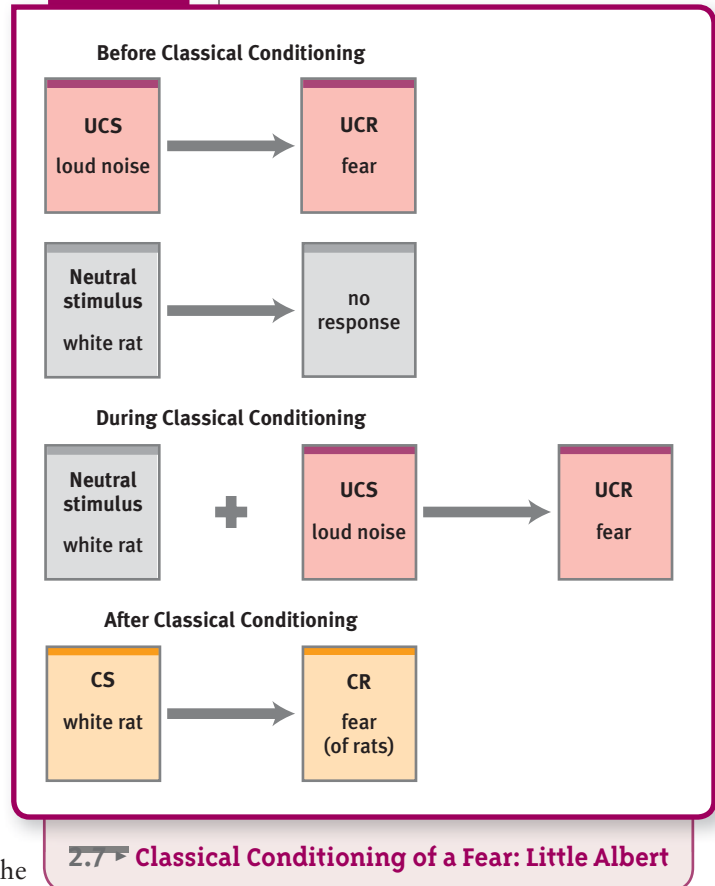

Although various reflexive behaviors, such as salivation, can be classically conditioned (Pavlov, 1927), the ones most important for understanding psychopathology are those related to emotional responses such as fear and arousal (Davey, 1987; Schafe & LeDoux, 2004). When emotions and emotion-related behaviors are classically conditioned, they are referred to as **conditioned emotional responses**. People who have the personality characteristic of being generally emotionally reactive—referred to as being high in *neuroticism*—are more likely to develop conditioned emotional responses than are people who do not have this personality characteristic (Bienvenu et al., 2001).

Conditioned responses can also *generalize*, so that they are elicited by stimuli that are similar to the conditioned stimulus, a process called **stimulus generalization**. For instance, Little Albert became afraid not only of white rats, but also of other white furry things. He even became afraid of a piece of white cotton! His fear of rats had generalized to similar stimuli.

As we shall see in detail in later chapters, classical conditioning is of interest to those studying psychological disorders because it helps to explain:

- various types of anxiety disorders, particularly phobias, like Little Albert's phobia;
- mechanisms related to substance abuse and dependence (Hyman, 2005);
- the development of specific types of sexual disorders (Domjan, Cusato, & Krause, 2004).

Figure 2.7

Unconditioned stimulus (UCS)

A stimulus that reflexively elicits a behavior.

Unconditioned response (UCR)

A behavior that is reflexively elicited by a stimulus.

Conditioned stimulus (CS)

A neutral stimulus that, when paired with an unconditioned stimulus, comes to elicit the reflexive behavior.

Conditioned response (CR)

A response that comes to be elicited by the previously neutral stimulus that has become a conditioned stimulus.

Conditioned emotional responses

Emotions and emotion-related behaviors that are classically conditioned.

Stimulus generalization

The process whereby responses come to be elicited by stimuli that are similar to the conditioned stimulus.

Operant conditioning

A type of learning in which the likelihood that a behavior will be repeated depends on the consequences associated with the behavior.

Reinforcement

The process by which the consequence of a behavior *increases* the likelihood of the behavior's recurrence.

Positive reinforcement

The type of reinforcement that occurs when a desired reinforcer is received after a behavior, which makes the behavior more likely to occur again in the future.

Negative reinforcement

The type of reinforcement that occurs when an aversive or uncomfortable stimulus is *removed* after a behavior, which makes that behavior more likely to be produced again in the future.

Punishment

The process by which an event or object that is the consequence of a behavior *decreases* the likelihood that the behavior will occur again.

Operant Conditioning

Operant conditioning is a type of learning in which the likelihood that a behavior will be repeated depends on the consequences associated with the behavior. Operant conditioning usually involves voluntary behaviors, whereas classical conditioning usually involves reflexive behaviors. With operant conditioning, when a behavior is followed by a positive consequence, the behavior is more likely to be repeated. Consider Big Edie's behavior of crying out for Little Edie to come back into the room. Little Edie then returns to the room (a positive consequence), making it more likely that Big Edie will cry out for Little Edie to return in the future. When a behavior is followed by a negative consequence, it is less likely to be repeated. For instance, the last time Big Edie left Grey Gardens was in 1968, when she and her daughter went to a party at a friend's house; upon returning home, the Beale women discovered that thieves had taken \$15,000 worth of heirlooms. It seemed to Big Edie that her behavior (leaving the house) was followed by a negative consequence (the theft), and so she never left again.

Psychologist B. F. Skinner showed that operant conditioning can explain a great deal of behavior, including abnormal behavior, and operant conditioning can be used to treat abnormal behaviors (Skinner, 1965). As we shall see throughout this book, operant conditioning contributes to various psychological disorders, such as depression, anxiety disorders, substance abuse disorder, eating disorders, and problems with self-regulation in general. Operant conditioning relies on two types of consequences: reinforcement and punishment.

Reinforcement

A key element in operant conditioning is **reinforcement**, the process by which the consequence of a behavior *increases* the likelihood of the behavior's recurrence. The consequence—an object or event—that makes a behavior more likely in the future is called a *reinforcer*. In the case of Big Edie's fear of being alone, the behavior was Big Edie's calling out to her daughter to return to her room, and it was followed by a reinforcer: Little Edie's return to her mother's side. The consequences do not need to be explicit in order for reinforcement to occur. That is, subsequent behavior change in response to reinforcement is likely to occur even when the individual is not *told* what behavior is being reinforced.

We need to consider two types of reinforcement: positive reinforcement and negative reinforcement. **Positive reinforcement** occurs when a desired reinforcer is received after the behavior, which makes the behavior more likely to occur again in the future. For instance, when someone takes a drug, the chemical properties of the drug may lead the person to experience a temporarily pleasant state (the reinforcer), which he or she may want to experience again, thus making the person more likely to take the drug again.

In contrast, **negative reinforcement** occurs when an aversive or uncomfortable stimulus is *removed* after a behavior, which makes that behavior more likely to be repeated in the future. For example, suppose that a man has a strong fear—a phobia—of dirt. If his hands get even slightly dirty, he will have the urge to wash them and will be uncomfortable until he does so. The act of washing his hands is negatively reinforced by the consequence of removing his discomfort about the dirt, which makes him more likely to wash his hands again the next time they get a bit dirty. Similarly, someone who feels sad and then eats some ice cream may briefly feel better; the act of eating the ice cream is negatively reinforced by the consequence of feeling less sad, which in turn increases the likelihood that the person will reach for ice cream the next time he or she feels sad. Negative reinforcement is often confused with punishment; as we see next, however, the two are very different.

Punishment

Positive reinforcement and negative reinforcement both *increase* the probability of a behavior's recurring. In contrast, **punishment** is a process by which an event or object that is the consequence of a behavior *decreases* the likelihood that the behavior will occur again. Just as there are two types of reinforcement, there are two types

of punishment: positive punishment and negative punishment. **Positive punishment** takes place when a behavior is followed by an undesirable consequence, which makes the behavior less likely to recur. In other words, an undesired stimulus is added in response to a behavior. For example, imagine that every time a young boy sings along with a song playing on the radio, his older sister makes fun of him (an undesirable consequence): In the future, he won't sing as often when she's around. That boy has experienced positive punishment.

Some parents use corporal punishment—spanking or slapping a child after a misbehavior—as positive punishment, believing that hitting a child after a misbehavior will decrease the likelihood of that behavior's recurring. Although a specific misbehavior may—or may not—become less likely if it is followed by corporal punishment, nonphysical forms of punishment can work just as well; examples of nonphysical punishments include time out and being grounded (Larzelere & Kuhn, 2005). (As we shall discuss shortly, though, these nonphysical punishments are *negative* rather than positive punishments.) Moreover, one reason to avoid using corporal punishment is that being physically punished in childhood may, for some children, lead to an increased risk of depression and substance abuse in adulthood (Afifi et al., 2006).

Negative punishment occurs when a behavior is followed by the removal of a pleasant or desired event or circumstance, which decreases the probability of that behavior's recurrence. Negative punishment occurs, for example, when a teenager stays out too late with friends and then her parents take away her access to television (or cell phone, email, use of the car, or something else she likes) for a week. Big Edie's father tried to use negative punishment to modify her behavior: He decreased her monthly allowance, repeatedly reduced her inheritance, and even told her that he was doing this because of her eccentric behavior. His attempts at negative punishment did not work, however, which indicates that the consequence he picked—taking away some money—was not meaningful enough to Big Edie.

The four types of operant conditioning are compared in Table 2.1.

Table 2.1 ▶ Four Types of Operant Conditioning

Type of Conditioning	How It Occurs	Result	Example
Positive Reinforcement	Desired consequence is produced by behavior.	Increased likelihood of the behavior	A pleasant effect from drug use makes drug use <i>more likely</i> to recur.
Negative Reinforcement	Undesired event or circumstance is removed after behavior.	Increased likelihood of the behavior	The uncomfortable feeling of having dirty hands is relieved by washing them (which makes such washing <i>more likely</i> to recur).
Positive Punishment	Undesired consequence is produced by behavior.	Decreased likelihood of the behavior	A sister's humiliating comment about her brother's singing along with the radio makes future singing in her presence <i>less likely</i> to recur.
Negative Punishment	Pleasant event or circumstance is removed after behavior.	Decreased likelihood of the behavior	Removing a television from a teenager's room after he stays out too late makes staying out too late <i>less likely</i> to recur.

Zave Smith/Getty Images

School detention is an attempt at positive punishment: Imposing the consequence of detention on students who exhibit troublesome behaviors should decrease the likelihood of those behaviors in the future.

Positive punishment

The type of punishment that takes place when a behavior is followed by an undesirable consequence, which makes the behavior less likely to recur.

Negative punishment

The type of punishment that takes place when a behavior is followed by the removal of a pleasant or desired event or circumstance, which decreases the probability of that behavior's recurrence.

Learned helplessness

The state of “giving up” that arises when an animal is in an aversive situation where it seems that no action can be effective.

Observational learning

The process of learning through watching what happens to others; also referred to as *modeling*.

Receiving frequent punishments or negative criticisms is associated with depression in some people: Over time, some individuals who experience such aversive events eventually give up trying to avoid or escape them and become depressed. Martin Seligman and his colleagues suggested that this giving up is learned through operant conditioning (Miller & Seligman, 1973, 1975). The process appears analogous to what happens to animals in similar circumstances. Consider a classic study by Overmier and Seligman (1967): When caged dogs were electrically shocked, at first they would respond to the shocks, trying to escape in order to avoid them. But when they could not escape the continued shocks, they eventually stopped responding and simply endured, huddling on the floor. Even after they were put in a new cage in which they could easily avoid the shocks, they remained on the floor. This phenomenon is called **learned helplessness**: In an aversive situation where it seems that no action can be effective, the animal stops trying to escape (Mikulincer, 1994). Learned helplessness may also occur in humans, and is considered to underlie certain types of depression. For example, sometimes people are emotionally abused—continually criticized, humiliated, and belittled—and no matter how hard they try to be “better” (and so prevent the abuse), the emotional abuse continues. When people in such a situation give up trying, they may become depressed and become vulnerable to a variety of stress-related problems.

FEEDBACK LOOPS IN ACTION: Classical Conditioning and Operant Conditioning Revisited

Classical conditioning and operant conditioning involve neurological factors: the underlying brain mechanisms that pair stimuli in the case of classical conditioning, and the underlying brain mechanisms for reward and punishment in the case of

operant conditioning. And based on temperament (another neurological factor, which we’ll discuss shortly), people who are more emotionally reactive are more likely to develop conditioned emotional responses than are others (Bienvenu et al., 2001). Social factors can also contribute to maladaptive learning: The presence of others or emotional responses from others can serve as reinforcement or punishment (Kringelbach, Arango, & Rolls, 2001), leading people to behave in maladaptive ways. For example, if a parent punishes a child in some way (even through facial expressions) for playing with another child, that punished child may grow up to feel that it is somehow “wrong” to enjoy others’ company and come to avoid others when possible. Similarly, a specific individual, such as a punitive relative, can become a conditioned stimulus, eliciting fear.

Let’s suppose that a student gave a presentation that didn’t go well and some classmates snickered during one part (social factor). Let’s also suppose that this student had an inherited vulnerability (a neurological factor; Biederman et al., 2001; Kagan, 1989) that increased his or her risk of developing a conditioned emotional response—in this case, to making presentations (Mineka & Zinbarg, 1995). And let’s further suppose that the student developed negative, irrational thoughts about public speaking (psychological factor; Abbott & Rapee, 2004; Antony & Barlow, 2002). The neurological factors and social factors may increase the likelihood that the student will develop a *social phobia*—an intense fear of public humiliation or embarrassment, accompanied by an avoidance of social situations likely to elicit this fear.

Observational Learning

Not all learning involves directly experiencing the associations that underlie classical and operant conditioning. **Observational learning** (also referred to as *modeling*)

Getty Images

People who are uncomfortable in particular social situations may leave such situations as early as possible; this early departure is negatively reinforced because, once they leave, they no longer feel uncomfortable. Such negative reinforcement of social anxiety can contribute to a psychological disorder called *social phobia*—unreasonable anxiety or fear in social situations (American Psychiatric Association, 2000).

results from watching what happens to others (social factor; Bandura, Ross, & Ross, 1961); from our observations, we develop a guide for our own behavior as well as expectations about what is likely to occur when we behave the same way (psychological factor). Observational learning is primarily a *psychological* factor: Mental processes (who and what behaviors are paid attention to, how the information is perceived and interpreted, how motivated the individual is to imitate the behavior) are a primary force. However, social factors are also involved, which include who the model is, his or her status, and his or her relationship to the observer. For instance, people who have high status or are attractive are more likely to hold our attention—so we are more likely to model their behavior (Brewer & Wann, 1998).

Through observational learning, children can figure out the types of behavior that are acceptable in their family (Thorn & Gilbert, 1998), even if the observed behaviors are maladaptive. For example, when children observe parents managing conflict through violence or by drinking alcohol, they may learn to use such coping strategies themselves. From a young age, Little Edie spent much of her time with her mother, and during the 2 years she was kept out of school, she was with her mother practically day and night. Thus, in her formative years, Little Edie had ample opportunity to watch her mother's eccentric behavior and may have modeled her own eccentric behavior on that of her mother. Further, observational learning and operant conditioning can work together: When Little Edie modeled her behavior after her mother's, she was no doubt reinforced by her mother.

Mental Processes and Mental Contents

As Freud emphasized (see Chapter 1), both mental processes and mental contents play important roles in the etiology of psychological disorders. Let's take a closer look at these two types of contributing factors.

Mental Processes

We all have biases in our mental processes; hearing the same conversation, we can differ in what we pay attention to, how we interpret what we hear, and what we remember. Suppose a group of friends is sitting around chatting after dinner. One of them says, "I feel really bad." Each friend may understand and respond to this sentence in a different way: One friend may pay a lot of attention to it, understand it to mean, "You've made me feel very bad by what you said earlier" (and then spend the rest of the night feeling guilty for inflicting emotional pain on someone else). Another friend may "tune out" the complaint and not even remember it later. A third friend may pay attention to it, but infer that the person is physically unwell and wonder whether to recommend seeing a doctor.

With some psychological disorders, mental processes involved in attention, perception, and memory may be biased in particular ways:

- **Attention** results in selecting or enhancing certain stimuli, including those that may be related to a disorder (van den Heuvel et al., 2005). Women with an eating disorder, for instance, are more likely than women without such a disorder to focus their attention on the parts of their bodies they consider "ugly" (Jansen, Nederkoorn, & Mulken, 2005).
- **Perception** results in registering and identifying specific stimuli, such as spiders or particular facial expressions of emotion (Buhlmann, Etcoff, & Wilhelm, 2006). As one example of bias in perception, depressed people are less likely than nondepressed people to rate neutral or mildly happy faces as "happy" (Surguladze et al., 2004).
- **Memory** involves storing, retaining, and accessing stored information, including that which is emotionally relevant to a particular disorder (Foa et al., 2000).

Cognitive distortions

Dysfunctional, maladaptive thoughts that are not accurate reflections of reality and contribute to psychological disorders.

Consider the disorder *hypochondriasis*, which is marked by a preoccupation with bodily sensations, combined with a belief of having a serious illness despite a lack of medical evidence. People suffering from hypochondriasis have a memory bias: They are better able to remember health-related words than non-health-related words (Brown et al., 1999), which is not surprising considering that the disorder involves a preoccupation with illness.

Thus, various mental processes can contribute to psychopathology by influencing what people pay attention to, how they perceive various stimuli, and what they remember. In turn, these alterations in mental processes influence the content of people’s thoughts by shifting their awareness of various situations, objects, and stimuli.

Mental Contents

The contents of people’s thoughts can play a role in the development of psychological disorders, as noted in Chapter 1. Psychiatrist Aaron Beck (1967) proposed that dysfunctional, maladaptive thoughts are the root cause of psychological problems. These dysfunctional thoughts are **cognitive distortions** of reality. An example of a dysfunctional belief is a woman’s conviction that she is unlovable—that if her boyfriend *really* knew her, he couldn’t love her. Cognitive distortions can make a person vulnerable to psychological disorders and are sometimes referred to as *cognitive vulnerabilities* (Riskind & Alloy, 2006). Beck (1967) also argued that recognizing these false and dysfunctional thoughts, and adopting realistic and adaptive thoughts, can reduce psychological problems. Cognitive distortions can arise as a result of maladaptive learning from previous experiences. A man with a classically conditioned fear of rodents, for instance, may come to believe that rodents are *dangerous* because of the fear and anxiety he experiences when he’s with them. Operant conditioning can also give rise to cognitive distortions. For instance, a child who is repeatedly rejected by her father can grow up to believe that nobody could love her. In this case, the conditioning could have occurred every time she tried to hug her father, if he removed her arms from his body and turned away. Several common cognitive distortions are presented in Table 2.2.

Table 2.2 ► Cognitive Distortions

Cognitive Distortion	Definition	Example
All-or-Nothing Thinking	Seeing things in black and white	You think that if you are not perfect, you are a failure.
Overgeneralization	Seeing a single negative event as part of a never-ending pattern of such events	While having a bad day, you predict that subsequent days will also be bad.
Mental Filter	Focusing too strongly on negative qualities or events to the exclusion of the other qualities or events	Although your overall appearance is fine, you focus persistently on the bad haircut you recently had.
Disqualifying the Positive	Not recognizing or accepting positive experiences or events, thus emphasizing the negative	After giving a good presentation, you discount the positive feedback you received and focus only on what you didn’t like about your performance.
Jumping to Conclusions	Making an unsubstantiated negative interpretation of events	Although there is no evidence for your inference, you assume that your boss didn’t like your presentation.
Personalization	Seeing yourself as the cause of a negative event when in fact you were not actually responsible	When your parents fight about finances, you think their problems are somehow your fault, despite the fact that their financial troubles weren’t caused by you.

Mental health professionals need to keep in mind, however, cultural factors that may contribute to what appear to be maladaptive cognitive distortions, but in fact reflect appropriate social behavior in a patient's culture. For instance, some cultures, such as that of Japan, have a social norm of responding to a compliment with a self-deprecating statement. It is only through careful evaluation that a clinician can discern whether such self-deprecating behavior reflects a patient's attempt to show good manners or his or her core maladaptive dysfunctional beliefs about self.

Biases in mental processes and distortions in mental contents affect each other (see Figure 2.8), and their interactions can make people more vulnerable to psychopathology. Unfortunately, once someone has a psychological disorder, these biases and distortions can become self-perpetuating: People see what they believe they will see. Someone who feels unlovable, for instance, becomes alert for—and will remember—any hint of rejection, which then confirms the belief of being unlovable.

Emotion

Part of being human is to know the ups and downs of emotions—such as joy, elation, happiness, love, pride, sadness, fear, anger, guilt, relief. When our emotions are negative—that is, when they make us feel uncomfortable—we often try to make ourselves feel better. When we are afraid, we try to avoid what's making us afraid or calm ourselves down; when we feel guilty, we seek to relieve the guilt. Yet not everyone experiences the normal range of emotions or is equally effective in regulating emotions. Many psychological disorders include problems that involve emotions: not feeling or expressing enough emotions (such as showing no response to a situation where others would be joyous or sad), having emotions that are inappropriate or inappropriately excessive for the situation (such as feeling sad to the point of crying for no apparent reason), or having emotions that are difficult to regulate (such as not being able to overcome a fear of flying, even though you know that such fear is irrational) (American Psychiatric Association, 2000).

But what, specifically, are emotions? To psychologists, an **emotion** is a short-lived experience evoked by a stimulus that produces a mental response, a typical behavior, and a positive or negative subjective feeling. The stimulus that initiates an emotion could be physical: It can be a kiss, the letter *F* on an essay you get back from a professor, or the sounds of a tune you listen to on your computer. Alternatively, the stimulus can occur only in the mind, such as *remembering* a sad occasion or tune or *imagining* your perfect mate.

Mental health clinicians and researchers sometimes use the word **affect** to refer to an emotion that is associated with a particular idea or behavior, similar to an *attitude*. *Affect* is also used to describe how emotion is expressed, as when noting that a patient has **inappropriate affect**—the patient's expression of emotion is not appropriate to what he or she is saying or not appropriate to the situation. An example is a person laughing at a funeral or talking about something very sad or traumatic while smiling, or, conversely, talking about a happy event while looking sad or angry. **Flat affect** is a lack of, or considerably diminished, emotional expression, such as occurs when someone speaks robotically and shows little facial expression. People with some psychological disorders, such as schizophrenia, frequently display inappropriate or flat affect. Affect that changes very rapidly—too rapidly—is said to be *labile*, and it may indicate a psychological disorder; for instance, some people with depression may quickly shift emotions from sad to angry or irritable.

In the film *Grey Gardens*, Little Edie and her mother often displayed inappropriate affect, and Little Edie's emotions were sometimes labile, rapidly changing from anger to happy excitement to relative calm. For instance, at one point, Big Edie recounts that when Little Edie had moved to New York City, Big Edie wanted Mr. Beale to return to Grey Gardens. Little Edie immediately started yelling, "You're making

Figure 2.8

2.8 ▶ Biased Mental Processes and Distorted Mental Contents

Biases in mental processes can influence the contents of people's thoughts by making certain stimuli more prominent and easier to call to mind, which can lead to cognitive distortions. The reverse is also true: Cognitive distortions can create a bias in what people pay attention to, perceive, and remember.

Girl Ray/Getty Images

Some disorders are characterized by inappropriate affect—expressions of emotion that are inappropriate to the situation. This young man appears to have inappropriate affect.

Emotion

A short-lived experience evoked by a stimulus that produces a mental response, a typical behavior, and a positive or negative subjective feeling.

Affect

An emotion that is associated with a particular idea or behavior, similar to an attitude.

Inappropriate affect

An expression of emotion that is not appropriate to what a person is saying or not appropriate to the situation.

Flat affect

A lack of, or considerably diminished, emotional expression, such as occurs when someone speaks robotically and shows little facial expression.

me very angry!” (Maysles & Maysles, 1976), even though one moment before she had been relatively calm, and they were talking about events that had transpired over 20 years earlier.

A **mood** is a persistent emotion that is not attached to a stimulus. A mood lurks in the background and influences mental processes, mental contents, and behavior. For example, when you wake up “on the wrong side of the bed” for no apparent reason and feel grumpy all day, you are experiencing a type of bad mood. Some psychological disorders, such as depression, involve disturbances in mood.

Emotions and Behavior

Emotions and behavior can be closely linked in various ways (see Figure 2.9). People are more likely to participate in activities and behave in ways that are consistent with their emotions (Bower & Forgas, 2000). When people are sad, they tend to hunch their shoulders and listen to slow music rather than upbeat music. When people are afraid, they tend to freeze, like a deer caught in the headlights. And when people are depressed, they often don’t have the inclination or energy to see friends, which can lead to social isolation. Fortunately, the relationship between emotions and behavior also works in

the other direction: A change in behavior can lead to a change in emotion. When depressed people make an effort to see friends or engage in other activities that they used to enjoy, they often become less depressed (Jacobson, Martell, & Dimidjian, 2001). The fact that changing behaviors can alter emotions is the basis of a number of psychological treatments (to be discussed in Chapter 4). The point is that emotions can kindle—and be kindled by—behavior; emotions and behavior dynamically interact.

Emotions, Mental Processes, and Mental Contents

Emotions not only affect behavior, but also affect mental processes and mental contents (see Figure 2.10). In fact, emotions and moods contribute to biases in attention, perception, and memory (Blaney, 1986; Eich, Macauley, & Ryan, 1994; Forgas, 1995; MacKay & Ahmetzanov, 2005; Mogg & Bradley, 2005; Yovel & Mineka, 2005). When anxious, people are more likely to judge a neutral stimulus as anxiety-related (Mogg & Bradley, 2005). Similarly, when feeling down, people are more likely to see the world through “depressed” lenses, to have a negative or pessimistic slant in general—not only will they find it easier to remember past periods of sadness, but they will also tend to view the future as hopeless; they will see more reasons to be sad than will people who aren’t down (Lewis & Critchley, 2003).

In addition, the causality also works in the other direction: Mental processes can affect emotions. For example, emotions are affected by attributions. That is, we all regularly try to understand why events in our lives occur, and thus make *attributions*, assigning causes for particular occurrences. A person’s mood can be affected by the attributions he or she makes. For instance, college students who tend to attribute negative events to general, enduring negative qualities about themselves (“I am stupid”) are more likely to become depressed after a negative event (such as getting a bad grade) (Metalsky et al., 1993).

One particular type of attribution can actually protect against depression: The *self-serving attributional bias* occurs when people typically attribute positive events—but not negative events—to their own personality traits. For example, suppose you receive a pay raise or a good grade. If you are prone to the self-serving bias, you will attribute this positive event to some enduring quality that you believe you possess: intelligence, perseverance, ability, or some similarly positive trait. This bias serves to increase or preserve a positive view of yourself. People who are depressed rarely display the self-serving attributional bias, which is con-

Figure 2.9

2.9 ▶ Emotions and Behavior An emotion often leads a person to behave in a particular way that matches the emotional state. By the same token, behavior that is not consistent with an emotional state can lead to a change in the emotion, bringing it more into line with the behavior.

Figure 2.10

2.10 ▶ Emotions, Mental Processes, and Mental Contents Emotions can influence what people pay attention to, perceive, and remember, and they can color the contents of people’s thoughts. The influence also operates in the other directions: Mental processes and mental contents can alter people’s emotions.

Mood

A persistent emotion that is not attached to a stimulus; it exists in the background and influences mental processes, mental contents, and behavior.

sistent with their negative view of themselves, their past, and their future (Mezulis et al., 2004). This bias, although present in all cultures, is less evident among members of Asian cultures than among members of Western cultures (Mezulis et al., 2004), perhaps because members of Asian cultures often tend to attribute positive events to the efforts of groups of people, not a single individual.

And, of course, emotion can affect the sorts of attributions we make. For instance, Walter Scott and colleagues (2003) found that, among depressed individuals, those who were irritable and hostile were more likely to blame their negative life events on others, whereas those who were predominantly sad were more likely to blame themselves for such negative events.

Emotions, Moods, and Psychological Disorders

Many psychological disorders are marked by impaired or inappropriate emotions, emotional experiences, or emotional expression. For example, excesses of mood, as occur in depression (prolonged and profound sadness) and mania (prolonged and inappropriate elation or euphoria), are part of mood disorders. And schizophrenia can involve flat affect—deficits in emotion expression. Furthermore, some *dissociative disorders*, which involve a separation of normally integrated mental processes, include the absence of the normal emotional experiences (Hunter et al., 2003).

Some psychological disorders, such as those that involve high levels of fear or anxiety, often are accompanied by emotions or moods that don't fit the context in which they arise (Davidson, Jackson, & Klein, 2000). We are all likely to feel anxious and afraid if faced with a car that seems to be out of control and barreling toward us, but most of us will not experience that same level of anxiety or fear when simply driving across a bridge, giving a presentation, seeing a spider, or getting a tetanus shot. As we shall see in Chapter 7, some people do experience such misplaced emotions.

In addition, psychological disorders may arise from or produce difficulty in *regulating* emotions—such as an inability to dampen down anxiety when its intensity is inappropriate. Difficulty in regulating emotions and related thoughts and behaviors can lead to three types of problems (Cicchetti & Toth, 1991; Weisz et al., 1997): (1) *Externalizing problems* are characterized by too little control of emotion and related behaviors, such as aggression, and by disruptive behavior. They are called externalizing problems because their primary effects are on others and/or their environment; these problems are usually observable to others. (2) *Internalizing problems* are characterized by negative internal experiences, such as anxiety, social withdrawal, and depression. Internalizing problems are so named because their primary effect is on the troubled individual rather than on others; such problems are generally less observable to others. (3) *Other problems* include emotional or behavioral problems that do not fit into these categories. This “other” category includes eating disorders and learning disorders (Achenbach et al., 1987; Kazdin & Weisz, 1998).

Significant difficulty in regulating emotions can begin in childhood and last through adulthood, forming the basis for some disorders. For example, *personality disorders* are inflexible and maladaptive stable personality traits that lead to distress or dysfunction (Gratz et al., 2006). As we discuss in Chapter 13, several personality disorders are characterized by difficulties in emotional regulation, marked by impulsive behavior or rapid changes in emotion. Problems in regulating emotion can also occur in some forms of eating disorders and substance-related disorders (Sim & Zeman, 2005; Thorberg & Lyvers, 2006).

Brain Bases of Emotion

Emotion is a psychological response, but it is also a neurological response. We can learn much about the psychological aspects of emotion by considering how it arises from brain function. For example, research by Richard Davidson and colleagues,

Fear involves a reflexive activation of the amygdala, not necessarily accompanied by any cognitive interpretation of the stimulus. Other emotions, such as guilt, depend on such interpretation. The ease of treating an emotional problem may be related to the nature of the underlying mechanism that gives rise to the experience of that emotion.

Temperament

The various aspects of personality that reflect a person's typical emotional state and emotional reactivity (including the speed and strength of reactions to stimuli).

conducted largely by measuring the brain's electrical activity, has demonstrated that there are two general types of human emotions, approach emotions and withdrawal emotions, each relying on its own system in the brain. *Approach emotions* are positive emotions, such as love and happiness, and tend to activate the left frontal lobe more than the right. *Withdrawal emotions* are negative emotions, such as fear and sadness, and tend to activate the right frontal lobe more than the left (Davidson, 1992a, 1992b, 1993, 1998, 2002; Davidson et al., 2000; Lang, 1995). Researchers have also found that people who generally have more activation in the left frontal lobe tend to be more optimistic than people who generally have more activation in the right. This is important because depression has been associated with relatively less activity in the left frontal lobe (Davidson, 1993, 1994a, 1998; Davidson et al., 1999). As a result of genetics, learning, or (most likely) some combination of the two, some people are temperamentally more likely to experience positive (approach) emotions, whereas others are more likely to experience negative (withdrawal) emotions (Fox et al., 2005; Rettew & McKee, 2005).

Joseph LeDoux (1996) has further suggested that different brain systems contribute to different emotions. This is important for psychopathology and its treatment because some of these systems lie outside of awareness and are not easy to control voluntarily. In contrast, other brain systems rely on conscious interpretation of stimuli or events, and hence might be more easily targeted during psychotherapy. In particular, LeDoux argues that some of the brain systems that underlie emotions work like reflexes, *independent* of conscious thought or interpretation. For example, fear involves activation of the amygdala, but not necessarily any cognitive interpretation of the stimulus (you become afraid before you've thought through the situation). Other emotions, such as guilt, *depend* on such cognitive processes. Why the difference? In our evolutionary past, fear may have been particularly important to survival, signaling the presence of an immediate danger—and hence it was advantageous to have a very rapidly acting brain system for identifying to-be-feared objects. Guilt is different; not only may the consequences often be less severe than those of fear-inducing events, but also the consequences of guilt-inducing events may not be as immediate as the threats that evoke fear—you can take your time responding to what made you feel guilty, wallowing in your guilt at your leisure.

Temperament

Temperament is closely related to emotion: **Temperament** refers to the various aspects of personality that reflect a person's typical emotional state and emotional reactivity (including the speed and strength of reactions to stimuli). Temperament is in large part innate, and it influences behavior in early childhood and even in infancy. Temperament is of interest in the study of psychological disorders for two reasons (Nigg, 2006): First, it may be part of the neurological vulnerability for certain disorders; having a particular temperament may make a person especially vulnerable to certain psychological disorders, even at an early age. For instance, people who are temperamentally more emotionally reactive are more likely to develop psychological disorders related to high levels of anxiety. Second, it is possible that in some cases a psychological disorder is simply an extreme form of a normal variation in temperament. For instance, some researchers argue that social phobia is on a continuum with shyness but is an extreme form of it; shyness involves withdrawal emotions and lack of sociability, and is viewed as a temperament (Schneider et al., 2002).

The Beale women had unusually reactive temperaments—reacting strongly to stimuli. One or the other of them would respond to a neutral or offhand remark with emotion that was out of proportion: hot anger, bubbling joy, or snapping irritability. It's not a coincidence that mother and daughter seemed similar in this respect. Much evidence indicates that genes contribute strongly to temperament (Gillespie et al., 2003); in fact, some researchers report that genes account for about

half of the variability in temperament (Oniszczenko et al., 2003). Researchers have associated some aspects of temperament to specific genes, such as genes that affect receptors for the neurotransmitter dopamine and a gene involved in serotonin production, and have shown that these genes can influence depression and problems controlling impulses (Nomura et al., 2006; Propper & Moore, 2006). Genes that affect dopamine receptors have also been shown to influence emotional reactivity (Oniszczenko & Dragan, 2005). However, these genes have stronger effects on children raised in harsh family environments, and, as we stressed earlier, the effects of genes need to be considered within the context of specific environments (Roisman & Fraley, 2006; Saudino, 2005).

Researchers and scholars going back at least as far as Plato in ancient Greece have proposed many ways to conceive of variations in temperament (Buss, 1995; J. A. Gray, 1991; Eysenck, 1990). C. Robert Cloninger and his colleagues have proposed one particularly influential contemporary theory of temperament, which describes temperament in terms of four dimensions—novelty seeking, harm avoidance, reward dependence, and persistence—each of which is associated with a brain system that relies predominantly on a particular neurotransmitter (Cloninger, 1987; Cloninger, Svrakic, & Przybeck, 1993).

Novelty seeking consists of searching out novel stimuli and reacting to them positively; this dimension of temperament also involves being impulsive, avoiding frustration, and losing one's temper easily. Novelty seeking is thought to be associated with the actions of dopamine (which is known to play a central role in the effects of reward on behavior). A high level of novelty seeking is associated with a variety of disorders that involve impulsive or aggressive behaviors (Yoo et al., 2006).

Harm avoidance consists of reacting very negatively to harm and, whenever possible, avoiding it. This dimension of temperament may be associated with the actions of serotonin (which, as noted earlier, is involved in mood and motivation). For instance, people with anxiety disorders tend to have higher levels of harm avoidance than do people without anxiety disorders (Ball, Smolin, & Shekhar, 2002; Rettew et al., 2006; Wiborg et al., 2005).

Reward dependence involves the degree to which behaviors that have led to desired outcomes in the past are repeated; for example, a person may continually seek out social approval because he or she has received approval in the past. This dimension of temperament is associated with the actions of norepinephrine (which plays a role in attention and the stress response). A low level of reward dependence, in combination with a high level of impulsivity, is found in people who have substance use disorders (Tcheremissine et al., 2003).

The fourth dimension of temperament is *persistence*, which consists of making continued efforts in the face of frustration when attempting to accomplish something. Originally, this dimension was viewed as an aspect of reward dependence (and hence affected by norepinephrine), but subsequent research has suggested that certain genes that lead to low levels of dopamine may be associated with it (Czermak et al., 2004). A low level of persistence is found in attention-deficit/hyperactivity disorder (Yoo et al., 2006).

In fact, researchers have found associations between specific genes and these dimensions of temperament (Gillespie et al., 2003; Keltikangas-Järvinen et al., 2006; Rybakowski et al., 2006). The specific results suggest that complex inheritance, not Mendelian inheritance, is at work. Temperament apparently arises from the joint activity of many different factors. However, not surprisingly, the underlying neurological bases for the four dimensions of temperament are more complex than originally conceived. For example, researchers have linked novelty and reward dependence with certain genes and with levels in the blood of a specific variant of *monoamine oxidase (MAO)*, an enzyme (Shiraishi et al., 2006); people who have low levels of MAO tend to seek out sensations by engaging in high-stimulation activities, such as sky diving (Zuckerman, 1994).

Skip Nall/Getty Images

Because of temperament, some people will avoid situations that have a risk of harm. Such people are more likely to have high levels of anxiety and to develop anxiety disorders.

Key Concepts and Facts About Psychological Factors in Psychological Disorders

- Three types of learning can contribute to psychological disorders:
 - Classical conditioning of emotional responses such as fear and anxiety. Conditioned emotional responses can generalize from the original conditioned stimulus to other, similar stimuli.
 - Operant conditioning of voluntary behaviors through positive and negative reinforcement and punishment. Certain types of depression in humans can be thought of as similar to learned helplessness in animals.
 - Observational learning, which can guide the observer's behaviors and expectations, leading to maladaptive behaviors.
- Mental processes and mental contents play important roles in the etiology and maintenance of psychological disorders.
 - Mental processes influence what people pay attention to, how they perceive and interpret various situations and events, and what they remember.
 - Mental contents can be associated with various psychological disorders in the form of irrational thoughts that are cognitive distortions of reality, creating cognitive vulnerabilities. Once someone has a psychological disorder, these biases and distortions can become self-perpetuating.
- Emotional disturbances contribute to some psychological disorders. Such disturbances include:
 - not feeling or expressing emotions to a normal degree;
 - expressing emotions that are inappropriate or inappropriately excessive for the situation; and
 - having difficulty regulating emotions.
- Emotions, behaviors, mental contents, and mental processes are often intertwined, and so disturbances in one will affect the others. For instance, emotional and mood disturbances can lead to biases in mental processes, and mental processes can affect emotions. Moreover, a person's attributions and mood can affect each other.
- Emotions involve both a psychological and a neurological response to a stimulus. Researchers distinguish between two basic types of emotions—approach (positive) and withdrawal (negative)—each of which relies on different brain systems. Some people are temperamentally more likely to experience approach emotions, whereas others are more likely to experience withdrawal emotions.
- Having a particular temperament may make a person especially vulnerable to certain psychological disorders, even at an early age. In some cases, a psychological disorder may be an extreme form of a normal variation in temperament. Evidence indicates that genes contribute strongly to temperament; however, the effects of genes need to be considered within the context of specific environments.
- Temperament is conceived of as having four dimensions: novelty seeking, harm avoidance, reward dependence, and persistence. Cloninger proposed that each of these dimensions is associated with the action of a particular neurotransmitter and is influenced by complex inheritance and other factors.

Social Factors in Psychological Disorders

We exist in a world filled with social forces: our relationships with family, friends, colleagues, and neighbors; the messages we receive through the media; the norms of our culture. These social forces help to shape who we become; they can help to protect us from developing psychological disorders, or they can make us more vulnerable to or exacerbate psychological disorders. Social forces begin to exert their influence before adulthood, and they can affect each generation differently, as a culture changes over time: For instance, the more recently an American is born, the more likely he or she is to develop a psychological disorder (Kessler et al., 2005), perhaps because of social trends such as the increased divorce rate, an increased sense of danger, and a diminished sense of local community (Twenge, 2000).

Consider Big Edie and Little Edie. The social factors that influenced them include their relationships with other members of their family, their financial circumstances, the prevailing community and cultural standards of appropriate behavior for women—and the discrimination they encountered. Let's examine each type of social factor—family, community, and culture—as well as the stress they can create, in more detail.

Family Matters

Certain aspects of family life form the basis for the type of attachment a child has to the primary caregiver, which influences how a child comes to view himself or herself and learns what to expect from other people. Other family-related social factors

include the style of interaction among family members, child maltreatment, and parental psychological disorders. All of these factors can contribute to the emergence or persistence of psychological disorders.

Family Interaction Style and Relapse

If family members exhibit hostility, voice unnecessary criticism, or are emotionally overinvolved, then the family environment is characterized by **high expressed emotion**. Based on what we know of the Beale women, their family environment would likely be classified as high expressed emotion. Consider these typical comments by Big Edie to her daughter: “Well, you made a rotten breakfast,” followed moments later by, “Everything is perfectly disgusting on account of you” (Maysles & Maysles, 1976). Big Edie and Little Edie were also clearly overinvolved with each other: They spent virtually all their waking hours together, participated in all aspects of each others’ lives, and responded to each other in exaggerated ways.

British researchers found that among people with schizophrenia, those whose families showed high expressed emotion were more likely to have the disorder recur; the same association between high expressed emotion and relapse has been found in other studies in the United States and China (Butzlaff & Hooley, 1998; Yang et al., 2004). This may be because high expressed emotion is associated with family members’ belief that the patient has the ability to control his or her symptomatic behaviors, which sometimes leads the family members to push the patient to change (Miura et al., 2004). Unfortunately, these exhortations may well backfire—instead of encouraging the patient to change, they may produce the sort of stress that makes the disorder worse! When family members are educated about the patient’s disorder and taught more productive ways of communicating with the patient, relapse rates generally decline (Miklowitz, 2004).

High expressed emotion is not associated with relapse in all cultural or ethnic groups; members of different groups interpret such emotional expression differently. Among Mexican American families, for instance, the family member with schizophrenia is more likely to have a recurrence if the family style is the less common one of being distant and aloof; high expressed emotion is not related to recurrence (Lopez et al., 1998). And among African American families, high expressed emotion is actually associated with a better outcome (Rosenfarb, Bellack, & Aziz, 2006). One possible explanation is that in African American families, confrontations are interpreted as signs of honesty (Rogan & Hammer, 1998) and may signal love and caring.

Child Maltreatment

Child maltreatment comes in various forms—neglect, verbal abuse, physical abuse, and sexual abuse—and is associated with a higher risk for a variety of psychological disorders (Cicchetti & Toth, 2005), including personality disorders (Battle et al., 2004; Bierer et al., 2003). Child maltreatment exerts its influence indirectly, through the following:

- *An altered bodily and neurological response to stress.* For instance, children who have been maltreated have higher baseline levels of cortisol than do children who have not been maltreated. Such alteration of the stress response in those who have been maltreated continues into adulthood (Tarullo & Gunnar, 2006; Watts-English et al., 2006).
- *Behaviors that are learned as a consequence of the maltreatment.* For instance, maltreatment may result in a type of learned helplessness, so the children are more likely to be victimized as adults (Renner & Slack, 2006).

High expressed emotion

A family interaction style characterized by hostility, unnecessary criticism, or emotional overinvolvement.

Michael Newman/Photo Edit

Although high expressed emotion is associated with relapse in a European-American family member with schizophrenia, this is not true among Mexican Americans; the likelihood of relapse of a patient with schizophrenia in a Mexican American family is higher when family members are emotionally distant. The family shown here does not appear to be emotionally distant.

Social support can lessen the detrimental after-effects of a stressful event such as an untimely death. People who do not have such support have a higher risk of developing a psychological disorder.

Mike Theiler/Getty Images

Social support

The comfort and assistance that an individual receives through interactions with others.

- *Biases in discriminating and responding to facial expressions.* For instance, children who have been physically abused are more likely to perceive photographs of faces as conveying anger than are children who have not been physically abused (Pollak et al., 2000).
- *Difficulties in attachment.* Children who have been maltreated are less likely to develop a secure type of attachment than are children who have not been maltreated (Baer & Martinez, 2006).
- *Increased social isolation.* For instance, children who have been physically abused report feeling more socially isolated than children who have not been physically abused (Elliot et al., 2005).

However, not everyone who experienced maltreatment as a child develops a psychological disorder (Haskett et al., 2006; Katerndahl, Burge, & Kellogg, 2005).

Parental Psychological Disorders

Another family-related factor that may contribute to psychological disorders is the presence of a psychological disorder in one or both parents (Pilowsky et al., 2006). It is difficult to pinpoint the specific mechanism responsible for this association, however, because it could be due to any number—or combination—of factors. For instance, a parent may transmit a genetic vulnerability for a psychological disorder to a child. Alternatively, the specific patterns of interaction between an affected parent and a child may lead to particular vulnerabilities in learning, mental processes, cognitive distortions, emotional regulation, or social interactions—any or all of which can increase the risk of a psychological disorder as the child grows older (Finzi-Dottan & Karu, 2006).

What is clear is that the association between a parent's having a psychological disorder and the increased risk of the child's later developing a psychological disorder isn't due solely to genetic vulnerability. One study found that when depressed mothers received treatment, their symptoms improved and so did their children's symptoms of anxiety, depression, and disruptive behaviors. Prior to their mother's successful treatment, a third of the children had symptoms severe enough to be classified as psychological disorders. The more positively a mother responded to her treatment, the less likely her children were to continue to have symptoms (Weissman et al., 2006).

Community Support

Social support—the comfort and assistance that an individual receives through interactions with others—can buffer the stressful events that occur throughout life (Silver & Teasdale, 2005). Conversely, a lack of social support can make people more vulnerable to various psychological disorders (Scarpa, Haden, & Hurley, 2006). College students who experience high levels of stress, for instance, are less likely to be depressed if they have relatively high levels of social support (Pengilly & Dowd, 2000). Here's another example of the buffering effects of social support: When people are exposed to trauma during military service, they are less likely to develop posttraumatic stress disorder—anxiety and other symptoms that arise as a result of experiencing a trauma—if they have strong social support when they return home (Dikel, Engdahl, & Eberly, 2005; King et al., 1998).

The Beale women did not have much social support in their extended family or community, but they had each other, which clearly played a role in limiting whatever distress they may have felt about their lifestyle and circumstances. Little Edie noted, "My mother really was the most extraordinary member of the family. She was always singing. . . . I was happy to be alone with mother because we created the sort of life we liked, and it was very private and beautiful" (Wright, 2006, p. 17). On another occasion, Little Edie said of their singing, "That's really the only thing that we live for really. That we love and enjoy"

(Graham, 1976). Had the Beale women not supported each other and shared good times, the symptoms of psychological disorders that they displayed might have been worse.

Social Stressors

Living in poverty is associated with a higher rate of psychological disorders. Another social factor associated with psychological disorders is discrimination. Let's examine these two factors—financial hardship and discrimination—in more detail.

Socioeconomic Status

Socioeconomic groups are defined in terms of education, income, and occupational level; these indicators are sometimes referred to collectively as *socioeconomic status (SES)*. People from low SES backgrounds have a higher rate of psychological disorders than people from higher SES backgrounds (Costello et al., 1996, 2003; Kessler et al., 1995; Mittendorfer-Rutz et al., 2004; Robins & Regier, 1991). Socioeconomic factors may contribute to the development of psychological disorders in several ways. One theorized mechanism is through **social causation**: socioeconomic disadvantages and stress *cause* psychological disorders (Freeman, 1994). Specifically, the daily stressors of urban life, especially as experienced by people in a lower socioeconomic level, trigger mental illness in those who are vulnerable. For instance, living with inadequate housing, very limited financial means, and few job opportunities corresponds to the stress component of the diathesis–stress model discussed in Chapter 1 (Costello et al., 2003). Case 2.1 describes Anna, whose depression was precipitated by financial stressors.

CASE 2.1 ► FROM THE OUTSIDE: Depression and Social Selection

Anna was a single mother in her 30s when she sought treatment for her depression. At the time, she was having difficulty getting out of bed and was struggling to maintain order and basic routines at home for herself and her children. She had separated from her husband and lost her job 5 years prior to her first visit to the clinic. Since that time she had been struggling financially. She had a number of part-time jobs to try to make enough money to keep her family fed and clothed. However, she was often short of funds and felt very worried and stressed by their straitened [sic] financial situation. She noted she often felt worse after the summer as she became overwhelmed by the demands of a new school year and the thought of Christmas. As a result of encountering difficulty finding a permanent full-time position, her confidence waned, and she feared that she had lost her job skills. She had recently returned to school to take some business courses to update and extend her qualifications. . . .

Anna expressed regrets about her divorce. She had not realized at the time what a massive and difficult journey it would prove to be. She regretted uprooting her children and found her worries about money very stressful and disconcerting because she had never had to worry about finances before. Anna was a committed and dedicated mother who, even as she struggled to feed her children, put on a happy face to hide her stress because she did not want to worry them.

(Watson, Goldman, & Greenberg, 2007, pp. 83–84)

Another mechanism that may be responsible for the connection between psychological disorders and low SES is **social selection**: The hypothesis that those who are mentally ill “drift” to a lower socioeconomic level because of their impairments (Mulvany et al., 2001; Wender et al., 1973); social selection is sometimes referred to as *social drift*. In fact, research suggests that the relationship between psychological disorders and SES cuts both ways: low SES both contributes to disorders and is a consequence of having a disorder (Conger & Donnellan, 2007; Fan & Eaton, 2001; Johnson et al., 1999; Shaw et al., 1998).

Social causation

The hypothesis that the daily stressors of urban life, especially as experienced by people in a lower socioeconomic level, trigger mental illness in those who are vulnerable.

Social selection

The hypothesis that those who are mentally ill “drift” to a lower socioeconomic level because of their impairments; also referred to as *social drift*.

A study by Jane Costello and colleagues (2003) tested the influence of social selection and social causation on psychopathology in children. These researchers tracked over 300 Native American children between the ages of 9 and 13 for 8 years; the children were seen annually. At the start of the study, over half of the children were living in poverty. Halfway through the study, a casino opened on the reservation, raising the income of all the Native American families and pulling a quarter of them above the poverty line. Before the casino opened, children whose families were below the poverty line had more psychiatric symptoms than children whose families were above it. After the casino opened, the number of psychiatric symptoms among children who were no longer living in poverty was the same as among those who had never lived in poverty. Once the socioeconomic disadvantages and accompanying family stress were removed, children functioned better and their symptoms improved, an outcome that supports the role of social causation in this setting (Rutter, 2003).

Discrimination

Being the object of discrimination is associated with an increased risk of distress and psychological disorders (Bhui et al., 2005; Chakraborty & McKenzie, 2002; Kessler, Mickelson, & Williams, 1999; Mays & Cochran, 2001; Simons et al., 2002; United States Public Health Service, 2001). Women, for example, may experience sexual harassment and assault, limitations on their freedom (such as a prohibition against working outside the home), or glass ceilings (unstated limits on social or occupational possibilities). Such experiences may lead to increased stress and vulnerability to psychological disorders. For instance, sexual harassment of women in the workplace is associated with subsequent increased alcohol use by those women (Freels et al., 2005; Rospenda, 2002). Similarly, members of ethnic, racial, or sexual minority groups may experience

The stigma and discrimination encountered by some gays and lesbians can make them—and others experiencing discrimination—more vulnerable to psychological disorders (Herek & Garnets, 2007; Mays & Cochran, 2001).

harassment at—or discrimination in—school, housing, or jobs, which can create a sense of powerlessness and lead to chronically higher levels of stress (Bhugra & Ayonrinde, 2001; Burke, 1984; Mills et al., 2004; Williams & Williams-Morris, 2000), which in turn increases the risk for developing psychological disorders.

Despite the increased risk for disorders that is associated with discrimination, American Blacks and Hispanics are no more likely to experience psychological disorders than are Whites (Kessler et al., 1994; Breslau et al., 2005, 2006). How can we understand this paradoxical finding? People from nonmajority ethnic groups may also experience more protective factors—factors that buffer the effects of discrimination (Breslau et al., 2006; Lee & Newberg, 2005). Protective factors include social support, a sense of ethnic identity, spirituality, and religious participation. When non-Whites do have a disorder, however, their

symptoms are more persistent than are those of Whites with the same disorder (Breslau et al., 2005). Moreover, non-Whites are less likely to receive treatment for their psychological disorders (United States Public Health Service, 2001).

Bullying

Whereas discrimination involves untoward behavior toward someone because of his or her status as a member of a particular group (based on ethnicity, race, religion, sexual orientation, or another characteristic), *bullying* involves untoward behavior that may be unrelated to the victim's membership in an ethnic, racial, or other

Max Whittaker/Getty Images

group. Research indicates that being a victim of childhood bullying can contribute to psychological problems in childhood and adulthood (Arseneault et al., 2008; Fosse & Holen, 2004; Kumpulainen et al., 1998), and it is particularly likely to lead to internalizing problems. (Bullying itself is one type of externalizing problem; Kaltiala-Heino et al., 2000; Kumpulainen et al., 1998.)

War

War often inflicts extreme and prolonged stress on soldiers and civilian victims. How an individual responds to the effects of war is determined by a variety of factors (discussed at length in Chapter 7), such as proximity to the fighting and the duration of combat. Since the mandated extended tours of duty for American soldiers in Iraq and Afghanistan, approximately 20% of returning troops have symptoms of posttraumatic stress disorder or depression (Tanielian & Jaycox, 2008).

Culture

Every culture promotes an ideal of healthy functioning—of a “normal” personality—and a notion of unhealthy functioning. These ideals differ somewhat from culture to culture and can shift over time (Doerfel-Baasen & Rauh, 2001). Some cultures, such as those of many Asian, Latin American, and Middle Eastern countries, are *collectivist*, placing a high value on getting along with others; in such cultures, the goals of the group (family or community) traditionally take precedence over those of the individual. In contrast, other cultures, such as those of Australia, Canada, the United Kingdom, and the United States, are *individualist*, valuing independence and autonomy; the goals of the individual take precedence over the goals of the group (Hui & Triandis, 1986). In either case, if an individual has personality traits that are different from those valued by the culture, other people’s responses to the person may lead him or her to feel humiliated and to develop poor self-esteem, which increases the risk of developing psychological disorders.

Culture Can Suppress or Facilitate Behaviors

The *problem suppression-facilitation model* (Weisz et al., 1987) addresses how culture can influence mental health and mental illness. According to the model, cultural factors—such as values, social norms, and accepted child-rearing practices—can affect a child’s behavior by minimizing or amplifying the child’s natural behavioral tendencies. Consider a child who has a tendency to be very energetic and active. Cultures such as that of China, which value the ability to sit still for long periods of time, seek to minimize such a behavioral tendency. Hong Kong schools require children to sit and focus on schoolwork for long periods of time, and the children are not allowed to leave their seats. From an early age, then, energetic and active children must learn how to control their behavioral tendencies. This contrasts with American culture, where the school day is organized to allow children in primary grades to move around the classroom frequently (Sandberg, 2002).

Acculturation

Moving from one culture to another often leads people to adopt the values and behaviors of the new culture, a process that is termed *acculturation*. This can be very stressful and can create tension between parents—who moved to the new culture as adults—and their children, whose formative years were spent in the new culture. As these children grow up, they may be forced to choose between the values and views of their parents’ culture and those of the new culture, which can be stressful and can make them more likely to develop psychological disorders (Escobar, Nervi, & Gara,

Collectivist cultures tend to emphasize getting along with others and rank the community’s well-being over the individual’s; these values are reversed in individualist cultures. Individuals whose personalities differ from their culture’s ideal may face humiliation and even discrimination and may come to see themselves in a negative light—all of which can make them more vulnerable to psychological disorders.

Canan Chu/Getty Images

2000). However, the degree to which acculturation is stressful and increases the risk for psychological disorders depends on other factors, such as the degree of difference in values between the native and new cultures, the reasons for leaving the native country (traumatic causes for leaving such as war and famine can have strong effects), the change in SES status that results from immigration, and the degree of discrimination encountered in the new culture. In the absence of these other factors, moving to a new culture is not necessarily associated with later psychological disorders (Kohn, 2002).

Paradoxically, individuals who have immigrated to the United States tend to have lower rates of psychological disorders than their American-born counterparts of similar age (Alegría et al., 2008; Nguyen, 2006). One possible explanation for this counterintuitive finding is that people who voluntarily leave their native countries to live elsewhere may be particularly psychologically hardy and better able to weather the stresses of immigration. Moreover, not all groups of immigrants are equally psychologically robust: Puerto Rican immigrants are afflicted with psychological disorders at the same rates as their American-born counterparts whose families immigrated earlier from Puerto Rico. Immigrants from Mexico, in contrast, are less likely to suffer from psychological disorders than are American-born people of Mexican descent (Alegría et al., 2008).

Key Concepts and Facts About Social Factors in Psychological Disorders

- Social factors can help to protect us from developing psychological disorders, or they can make us more vulnerable to or exacerbate psychological disorders. Such factors begin to exert their influence before adulthood and can affect each generation differently, as a culture changes over time.
- A family's style of interacting that involves high expressed emotion can contribute to relapse in patients with schizophrenia from particular ethnic or cultural groups.
- Being maltreated as a child indirectly contributes to the development of psychological disorders by:
 - increasing stress,
 - teaching maladaptive behaviors,
 - promoting biases in discriminating among and responding to facial expressions,
 - creating difficulties in attachment, and
 - increasing social isolation.
- Psychological disorders in parents can contribute to psychological disorders in their children, although it is difficult to pinpoint the specific mechanism through which this influence occurs.
- Social support can buffer against stress, and a lack of social support can make people more vulnerable to psychological disorders.
- Low SES is associated with a higher rate of psychological disorders; both social causation and social selection contribute to this relationship.
- Being the object of discrimination is associated with an increased risk of distress and psychological disorders.
- Different personality traits and behaviors are valued in different cultures; thus, acculturation can lead to conflict among family members, creating stress and a risk of psychological disorders.

Feedback Loops in Action: Learned Helplessness

We have stressed that neurological, psychological, and social factors do not occur in isolation, but rather affect each other. Let's examine the phenomenon of *learned helplessness* in more detail to understand the feedback loops between the three sorts of factors (Zhukov & Vinogradova, 1998). Consider that when rats receive uncontrollable shock (as compared to controllable shock), neurological events in the brain change (Amat et al., 2001); for example, serotonin levels decrease (Amat et al., 1998; Edwards et al., 1992; Petty, Kramer, & Wilson, 1992), and the density of receptors for the neurotransmitter GABA increases in particular brain regions (Kram et al., 2000). Furthermore, rats can be bred to be more inclined or more resistant to developing learned helplessness, which suggests that genetic factors may contribute to whether a rat is vulnerable to this outcome (Kohen et al., 2003).

Moreover, studies of rats have also demonstrated the influence of social factors. For example, in one study, rats received inescapable shocks either alone or in pairs. The pairs of rats fought when shocked. But these rats, when tested individually 2 days later, were less likely to show learned helplessness than the rats that were originally shocked alone (Zhukov & Vinogradova, 1998). Perhaps the fighting helped to distract the paired rats from the shocks, or perhaps the neural events that provoked the rats to fight also protected them from subsequent learned helplessness.

What does this have to do with humans? Consider the fact that social factors can create an aversive situation from which an individual cannot escape, such as abuse (physical, sexual, or emotional), social discrimination, or poverty (for Anna, in Case 2.1). Characteristics of the environment, such as uncontrollable noise and crowding, are associated with a learned helplessness response (Evans & Stecker, 2004). These events lead to changes in psychological factors, such as the individual's beliefs ("I can't escape, so I might as well give up"), goals ("No matter what I do it doesn't help, so I must simply endure it"), and behavior (staying put). In turn, these events lead to neurological changes, such as a reduced serotonin level in the brain, which is associated with depression. And we've already seen how learned helplessness may contribute to some cases of depression.

Let's conclude this chapter by briefly examining how neurological, psychological, and social factors might have affected each other via feedback loops in the case of Big Edie and Little Edie. Both women were artistic, unconventional, and independent (psychological factor), but their social class and the time in which they lived made their behavior "inappropriate," leading them to be discriminated against within their extended family and community (social factor). In turn, the social constraints of their day prevented them from having jobs or careers, and so they were unable to support themselves; they were financially dependent on others (social), which created its own stress (neurological and psychological). These external realities, in turn, may have heightened their feeling that people were out to get them (psychological factor). Moreover, it is possible that they had neurological characteristics—such as emotional reactivity—that predisposed them to behave in certain ways, which in turn evoked certain responses from others.

We will draw on the neuropsychosocial approach—considering all three types of factors *and their feedback loops*—to understand the various psychological disorders discussed in this book. Neurological factors (genetics, brain structure and function, and bodily responses), psychological factors (learning and behavior, mental processes and mental contents, and emotions), social factors (social stressors, relationships, family, culture, and socioeconomic status), and the interactions among these factors all play a role in explaining psychological disorders.

SUMMING UP

Summary of Neurological Factors

The nervous system has two major parts: the central nervous system (CNS), which is composed of the brain and spinal cord, and the peripheral nervous system (PNS), which is composed of the sensory-somatic nervous system and the autonomic nervous system (ANS). The ANS controls many involuntary functions, such as those of the heart, blood vessels, and digestive tract. The ANS has two major components: (1) The sympathetic nervous system produces more adaptive bodily

functioning in an emergency with the fight-or-flight response. As part of this response, the hypothalamic-pituitary-adrenal axis (HPA axis) manages the production of cortisol, which helps the muscles prepare for physical exertion. The HPA axis and high levels of cortisol are involved in depression and stress-related psychological disorders. (2) The parasympathetic nervous system typically brings the body back to its normal state after a fight-or-flight response.

The brain is divided into two hemispheres, which each have four major lobes: occipital lobe, parietal lobe, temporal lobe, and frontal

lobe. Subcortical (beneath the cortex) areas of importance are as follows: (1) the limbic system, which includes the hypothalamus, the amygdala, and the hippocampus; (2) the thalamus; (3) the nucleus accumbens; (4) the basal ganglia; and (5) the cerebellum.

There are three types of neurons: sensory neurons, motor neurons, and interneurons (most neurons are interneurons). Neurons communicate with each other to create patterns of activation—brain circuits—which are organized into large brain systems; these systems may be disrupted in cases of psychopathology. A neuron has a cell body, an axon that

ends in terminal buttons, and dendrites that receive signals from other neurons. The neuron is covered by a cell membrane that has channels that open when the neuron fires. When a neuron fires, neurotransmitters released from the terminal button travel across the synaptic cleft to receptors on the dendrite or cell body of another neuron. Neuromodulators may affect the functioning of neurotransmitters by altering events at the synapse.

Neurotransmitter substances include dopamine, serotonin, acetylcholine, adrenaline and noradrenaline, glutamate, GABA, and endogenous cannabinoids.

Neurotransmitters can bind to different types of receptors; the type of receptor a neurotransmitter binds to determines its effect. Neuronal communication can go awry when (1) neurons have an abnormal number of dendrites or receptors, affecting sensitivity to neurotransmitters in the synapse; (2) sending neurons release abnormal amounts of neurotransmitter into the synapse; (3) reuptake of neurotransmitter molecules does not operate correctly. Hormones, produced by glands in the endocrine system, often function as neuromodulators; an important hormone related to some psychological disorders is cortisol.

Genes can influence the development of psychopathology. Complex inheritance best explains the influence of genes on psychological disorders. Scientists who study behavioral genetics seek to determine the roles of genes, the environment, and their interactions in both normal and abnormal thoughts, feelings, and behaviors. Heritability is an estimate of how much of the variation of a characteristic across a population, *in a specific environment*, is determined by genes.

Behavioral geneticists may use twin and adoption studies to determine the relative influences of genes and environment. Twins may be monozygotic or dizygotic. Genes can affect the environment in three ways: (1) passive interaction, (2) evocative interaction, and (3) active interaction.

Thinking like a clinician

Dominic is adopted, and his biological father was an alcoholic; alcoholism has a genetic component. Dominic's adoptive parents are very religious and don't drink alcohol. What factors in Dominic's environment might affect the expression of any genes that he might have that can contribute to alcoholism? Suppose scientists determine that, among alcoholics, a particular brain area has an abnormally high level of activity of the neurotransmitter dopamine. Further suppose that Dominic has too much activation of dopamine neurons in this area. Does this mean that his brain is wired wrong, and he should just resign himself to eventually becoming an

alcoholic? How might psychological and social factors affect dopamine levels?

Summary of Psychological Factors

Three types of learning can contribute to psychological disorders: (1) Classical conditioning of emotional responses, such as fear and anxiety, produces conditioned emotional responses that can generalize from the original conditioned stimulus to other, similar stimuli. (2) Operant conditioning of voluntary behaviors occurs through positive and negative reinforcement and positive and negative punishment. (3) Observational learning can guide the observer's behavior and expectations, leading to maladaptive behaviors.

Mental processes and mental contents play important roles in the etiology and maintenance of psychological disorders. Mental processes influence what people pay attention to, how they perceive and interpret various situations and events, and what they remember. Mental contents can be associated with various psychological disorders in the form of irrational thoughts that are cognitive distortions of reality, creating cognitive vulnerabilities.

Emotional disturbances such as the following contribute to some psychological disorders: not feeling or expressing emotions to a sufficient degree, expressing emotions that are inappropriate or inappropriately excessive for the situation, and having difficulty regulating emotions. Emotions, behaviors, mental contents, and mental processes are often intertwined, and so disturbances in one will affect the others. Moreover, a person's attributions and mood can affect each other.

Researchers distinguish between two basic types of emotions—approach (positive) and withdrawal (negative)—each of which relies on different brain systems. Some people are temperamentally more likely to experience approach emotions, whereas others are more likely to experience withdrawal emotions.

Having a particular temperament may make a person especially vulnerable to certain psychological disorders, even at an early age. In some cases, a psychological disorder may be an extreme form of a normal variation in temperament. Evidence indicates that genes contribute strongly to temperament; however, the effects of genes need to be considered within the context of specific environments.

Temperament is conceived of as having four dimensions: novelty seeking, harm avoidance, reward dependence, and persistence.

Thinking like a clinician

Maya is depressed; she's often tearful and feels hopeless about the future and helpless

to change the negative things in her life. Give specific examples of the ways that types of learning might have influenced her negative expectations of life and led to her current depression. (It's okay to speculate here, but be specific.) Based on what you have read, how can Maya's thought patterns and emotions lead to her feeling depressed (or make the depression worse)?

Summary of Social Factors

Social factors can help to protect us from developing psychological disorders, or they can make us more vulnerable to or exacerbate psychological disorders. Such factors begin to exert their influence during childhood and can affect each generation differently, as a culture changes over time.

A family's style of interacting that involves high expressed emotion can contribute to relapse in patients with schizophrenia from particular ethnic or cultural groups. Being maltreated as a child indirectly contributes to psychological disorders by increasing stress, teaching maladaptive behaviors, promoting biases in discriminating among and responding to facial expressions, creating difficulties in attachment, and increasing social isolation. Psychological disorders in parents can contribute to psychological disorders in their children, although it is difficult to pinpoint the specific mechanism through which this influence occurs.

Social support can buffer against stress, and a lack of social support can make people more vulnerable to psychological disorders. Low SES is associated with a higher rate of psychological disorders; both social causation and social selection contribute to this relationship. Being the object of discrimination is associated with an increased risk of distress and psychological disorders. Different personality traits and behaviors are valued in different cultures; thus, acculturation can lead to conflict among family members, creating stress and a risk of psychological disorders.

Thinking like a clinician

Gonsalvo and Bill, roommates, are both first-year college students. Gonsalvo has left his family and country and moved to another continent to study in the United States; Bill's family lives a few hours' drive away. What social factors may influence whether either young man develops a psychological disorder during the time at college? Be specific about possible factors that might lead *each man* to be vulnerable. What social factors may protect them from developing a disorder? What additional information would you want to help you answer these questions, and how might such information affect your predictions?

Summary of Feedback Loops in Action

Research has demonstrated that rats that receive uncontrollable shocks undergo different brain changes (neurological factor) than do rats that receive controllable shocks. When a second rat is present during the shocks (social factor), subsequent behavior indicates that learned helplessness is less severe than occurs when rats are shocked alone. Similar mechanisms may contribute to depression in humans, which is associated with behavior that resembles learned helplessness. In humans, social factors such as abuse, discrimination, and poverty can lead to changes in beliefs (psychological factor), as well as changes in the brain (neurological factor) that are associated with depression.

Thinking like a clinician

Always a shy child, Lara vividly remembered the time in high school when it had been her turn to read aloud from a short story she'd written: She began blushing as soon as she got up in front of the class, she stumbled over her words, and the class roared with laughter at a part that wasn't meant to be funny. She felt humiliated and had nightmares about it for weeks. In college she tried to avoid classes that required class presentations.

Using the neuropsychosocial approach, point out the various factors likely to have contributed to Lara's fear of public speaking, and how those factors may have interacted with one another. In order to answer this question fully, what other information might you want to know about Lara's life, and why?

Clinical Diagnosis and Assessment

Jeannette Walls had an unusual childhood. She and her three siblings—Lori, Brian, and Maureen—had smart, engaging parents who taught them each to read by the time they were 3, explained and demonstrated to them scientific principles, instilled a love of reading and appreciation for the arts, and made their children each feel that they were special. As Jeannette Walls recounts in her memoir, *The Glass Castle* (2005), her father, Rex, was an intelligent man who was a skilled electrical engineer. Her mother, Rose Mary, was an artist and had been trained to be a teacher. Yet Rex had difficulty holding onto jobs, and most of the time Rose Mary didn't have a paying job. However, she wasn't as busy raising her children as you might think: Both parents gave their children enormous freedom to explore and experiment; they also often left the children to fend for themselves.

Rex and Rose Mary would uproot and move the family in the middle of the night, sometimes giving the kids 15 minutes to pack their things and pile into the car. They'd leave town in order to avoid bill collectors or child welfare officials, moving to whatever small town caught Rose Mary's and Rex's fancy. Neither parent spent much time fulfilling the many daily responsibilities of parenting, such as preparing meals. For instance, even at the age of 3, if Jeannette was hungry, she knew not to ask her parents for something to eat, but to make it herself. She figured out how to make hot dogs: put water in a pot and boil the dogs, standing on a chair by the gas stove in order to do it. During one stint of hot dog making when she was 3, her dress caught on fire. She was so severely burned that she was hospitalized for 6 weeks and had skin grafts. Her hospital stay ended when her father had a fight with her doctor about whether her bandages should remain on; her father carried Jeannette from her hospital room in the middle of the night and out to the car, where her family was waiting for her. They headed out of town to wherever the road took them; Jeannette's scars never properly healed.

The family referred to this and other late night moves from one dusty town to another as doing "the skedaddle." A few months after taking Jeannette out of the hospital, the family did the skedaddle again. During Jeannette's early childhood, Rex would get a job as an electrician or an engineer (often making up stories about previous jobs he'd had or degrees he'd earned). When they left a town, Rex

Diagnosing and Assessing Rose Mary and Rex Walls

would explain to the family that they were running from federal investigators, who were chasing him for some unnamed episode in the past; Rose Mary admitted to the children that frequently they were running from bill collectors. Sometimes they moved simply because Rex was bored.

Rex and Rose Mary tried to make their tumbleweed life into an adventure for their children, and they succeeded to some extent when the children were young. However, the parents' own problems got in the way of their responsibilities. When Rex would lose his job, sometimes he'd stay home. He drew up blueprints for a solar-powered "glass castle" or worked on his design for a tool that would find gold in rocks. And increasingly during Jeannette's childhood, he'd gamble and drink (where he found the money for liquor wasn't always clear, but sometimes he took the family's food money or his children's earnings from their part-time jobs). In what Jeannette describes as his "beer phase," Rex would drive fast and sing loudly. When he began to drink the "hard stuff," Rose Mary would get frantic because Rex would become angry: He'd beat his wife, throw furniture around, and yell. Then, he'd collapse.

When Jeannette was in elementary school and high school, her family was so poor that the children ended up eating only one meal a day—the lunch leftovers at school that they were able to scavenge from the trash. Under duress from her children and the threat of visits from child welfare officials, Rose Mary tried two different stints of working as a teacher, but she hated it so much that she had a hard time getting out of bed to get ready for work, and she had difficulty doing the paperwork required by the job. After a year, Rose Mary refused to work anymore; she claimed that she needed to put herself first—to paint, sculpt, and write novels and short stories—even though Rex still was not working and there was no other regular income.

Did Rex and Rose Mary have psychological disorders? To answer that question, we must return to the criteria for a psychological disorder that we discussed in Chapter 1: a pattern of thoughts, feelings, or behavior that lead to distress, impairment in daily life, and risk of harm, in the context of the culture. Did Rose Mary or Rex experience significant distress? Remarkably, Jeannette's account of her family conveys little sense that her parents were distressed by their situation. What about impaired functioning? The fact that neither parent was able to hold a job consistently certainly indicates impairment in daily life.

With regard to risk of harm, Rose Mary and Rex put themselves and their children at risk countless times in various ways: They—and their children—regularly went without food (and neither parent was sufficiently motivated to earn money in order to buy food). Rex repeatedly drove while intoxicated, sometimes at 90 miles an hour or more. The family members' physical safety was put at risk in other ways. Jeannette recalls how her parents insisted that the doors and windows of the house be left open at night for better air circulation, but vagrants would come in. One night when Jeannette was 10 years old, she woke up to find a vagrant sexually groping her. When the children asked their parents to close the doors at night, their parents refused: "They wouldn't consider it. We needed the fresh air, they said, and it was essential that we refuse to surrender to fear" (Walls, 2005, p. 103). The parents put themselves at risk of harm in other ways, including intense fighting. For example, during one fight, Rex and Rose Mary went at each other with knives—and then their fighting suddenly switched off, and the couple ended up laughing and hugging. Rose Mary admitted to her children that she was an "excitement addict," and her quest for excitement and Rex's drinking and related behavior often led the family into dangerous situations.

According to Jeannette's descriptions, then, both Rex and Rose Mary Walls would seem to have had some type of psychopathology. On what basis should you evaluate and classify their behavior? How would a mental health professional go about identifying their psychological problems? How should you go about determining whether a specific diagnosis is warranted? For mental health professionals,

a **diagnosis** is the identification of the nature of a disorder (American Psychiatric Association, 2000). A diagnosis is made by assigning a patient's symptoms to a specific classification. Classifying a set of symptoms as a disorder allows you to know more than was initially apparent. By analogy, once you've categorized an object as an "apple," you know that it has seeds inside, can be squeezed to produce juice or cider, and may have a relationship with the absence of doctors. Depending on how much is known about a given disorder, a diagnosis may suggest the disorder's possible causes, its course over time, and its possible treatments. In Rex's case, for example, a diagnosis for his pattern of drinking and related behavior would be what mental health clinicians call *alcohol dependence* (which we discuss in more detail in Chapter 9). Having a diagnosis might indicate why he—and other people with the same set of symptoms—may have developed the disorder and whether the symptoms would be likely to shift in frequency or intensity over time. Moreover, the diagnosis might indicate that certain types of treatment, such as those based on behavioral principles (see Chapter 2), might be more effective than other types of treatment (we will discuss different types of treatment in detail in Chapter 4).

A diagnosis is based on information about the patient obtained through interviews, observations, and tests. Such information is part of a **clinical assessment**—the process of obtaining relevant information and making a judgment about mental illness based on the information. Clinical assessments often go further than providing information needed to make a diagnosis. They also can provide information about the specific ways in which and the degree to which an individual is impaired, as well as about areas of functioning that are not impaired. When we discuss the mental health—or mental illness—of Rex and Rose Mary Walls, we are trying to approximate a clinical assessment based on the words—and judgments—of their daughter, Jeannette—someone who knew them intimately. Rex died at the age of 59. Were he alive today and it were possible to make a clinical assessment of him and Rose Mary, we would be in a position to determine with greater confidence whether either of them could be diagnosed with a psychological disorder.

Diagnosing Psychological Disorders

Rose Mary and Rex Walls created an endurance contest for their growing children. A typical example was when Lori was diagnosed by the school nurse as severely near-sighted and in need of glasses. Rose Mary didn't approve of eyeglasses, commenting, "If you had weak eyes . . . they needed exercise to get strong" (Walls, 2005, p. 96). Rose Mary thought that glasses were like crutches. She herself had refused to wear glasses for years, and initially refused to get glasses for Lori; she relented when school officials required the glasses for Lori to attend school.

Rose Mary also had entrenched illogical and dysfunctional beliefs about the importance of keeping land in the family and not selling it under any circumstance. After Rose Mary's mother died (when Jeannette was 9 years old), Rose Mary inherited property in Texas. That property was worth a lot of money (nearly \$1 million), yet she refused to sell it, despite the fact that she and her children lived in poverty, with no electricity, no indoor plumbing, no heat, and not enough food.

Rose Mary wasn't the only parent with unusual beliefs. Rex recounted to his family that the reason he hadn't found a job after months of unemployment in a coal mining town was because the mines were controlled by the unions, which were controlled by the mob, and he was nationally blackballed after he was kicked out of the electrician's union in Arizona (where he had previously worked). In order to get a job in the mines, he explained, he must help reform the United Mine Workers of America. And so he claimed that he spent his days investigating that union.

Diagnosis

The identification of the nature of a disorder.

Clinical assessment

The process of obtaining relevant information and making a judgment about mental illness based on the information.

Unusual beliefs may not have been the only factor that motivated Rose Mary and Rex's behavior; they also seemed to have a kind of tunnel vision that led them to see their own needs and desires while being indifferent to those of their children. When Jeanette was 5 and the family was again moving, her parents rented a U-Haul truck and placed all four children (including the youngest, Maureen, who was then an infant) and some of the family's furniture in the dark, airless, windowless back of the truck for the 14 hours it would take to get to their next "home." Rex and Rose Mary instructed the children to remain quiet in this crypt—which was also without food, water, or toilet facilities—for the entire journey. The parents also expected the children to keep baby Maureen silent so that police wouldn't discover the children in the back: It was illegal to transport people in the trailer. What explanation did the parents give their children for locking them up this way? They said that only two people could fit in the front of the truck.

In order to determine whether Rex and Rose Mary Walls had psychological disorders, we would have to compare their behavior and psychological functioning to some standard of normalcy. A diagnostic *classification system* provides a means of making such comparisons. We saw in Chapter 1 that various classification systems were used over the centuries; these systems categorized different types of disorders according to different principles. The ancient Greeks, for instance, classified mental disorders based on behavior that was attributed to either too much or too little of bodily humors.

The first modern classification system for characterizing mental disorders was developed by Emil Kraepelin (1856–1926), a distinguished German psychiatrist (Boyle, 2000). Kraepelin focused on both the symptoms themselves and their *course*—how they progressed over time. Through systematic and lengthy observations of patients, he outlined some of the hallmarks of what would later be called *schizophrenia*. Today's modern diagnostic system is based, in part, on Kraepelin's system.

Let's first examine general issues about classification systems and diagnosis and then consider the system that is now most commonly used—the system described in the most recent edition of the *Diagnostic and Statistical Manual of Mental Disorders*.

Why Diagnose?

You've probably heard that categorizing people is bad: It pigeonholes them and strips them of their individuality—right? Not necessarily. Imagine that classification systems for psychological disorders did not exist—that different sorts of unusual behavior could be described, but there were no labels for them. For instance, suppose that the diagnosis "depression" didn't exist. How, then, could clinicians and patients distinguish between a common response to a negative event (such as having a relationship break up)—feeling sad, rejected, and unlovable—and an episode of depressed mood that might lead to a suicide attempt or to chronic alcohol abuse? Moreover, without a classification system and the consequent ability to label disorders, such as depression, there would not be a word or a phrase to describe people's experiences. Said another way, there would be no yardstick of normality against which to measure people's experiences—their thoughts, feelings, and behaviors. It would therefore be difficult for clinicians and researchers to learn from one case to the next or to decide how best to help each person with unusual symptoms or combinations of symptoms.

By categorizing psychological disorders, clinicians and researchers can know more about a patient's symptoms and about how to treat the patient. To be specific, classification systems of mental disorders provide the following benefits:

- *They provide a type of shorthand, which enables clinicians and researchers to use a small number of words instead of lengthy descriptions.* For instance, Kitty Dukakis, wife of 1988 Democratic presidential candidate Michael Dukakis, suffered from depression (Dukakis & Scovell, 1991). By using the term *depression*,

AP Photo/Evan Agostini

Simone Lins/AFP/Getty Images/Newscom

Jason Moore/ZUMA Press/Newscom

clinicians don't need to spell out the various elements that constitute her disorder: for example, that she had depressed mood and a significant lack of energy and enthusiasm (Dukakis & Tye, 2006).

- *They allow clinicians and researchers to group certain abnormal thoughts, feelings, and behaviors into unique constellations.* To say that someone has a diagnosis of depression effectively communicates to a mental health professional that the patient has a particular constellation of symptoms. When a clinician hears that Kitty Dukakis suffered from depression, for instance, the clinician can infer that she has some or all of the following symptoms: depressed mood, reduced pleasure in activities, fatigue or tiredness, a sense of worthlessness, difficulty concentrating, recurrent thoughts about death, and significant changes in appetite, sleep, and energy level (American Psychiatric Association, 2000). Notice how long this list of symptoms is—the term *depression* conveys much of the needed information more succinctly.
- *A particular diagnosis may also convey information about the etiology (causes) of the disorder, its course, and indications for its treatment.* Depression, for instance, can further be specified as either a single—that is, first—episode or as a recurrence. A diagnosis of recurrent depression implies a heightened neurological and/or cognitive vulnerability to depression and a longer and more variable course, and it indicates that the disorder may require multiple types of treatments in order to reduce symptoms (Peterson et al., 2007). Despite treatment, Kitty Dukakis suffered numerous bouts of depression, which suggests that many types of factors contributed to her disorder and that she was at significant risk for additional episodes.
- *Classification systems also enable researchers to study the causes, the course, and the effects of treatments for various disorders.* If there were no diagnoses, then how would researchers be able to study mental illness and its treatment? They wouldn't be able to group together individuals with similar problems systematically and reliably. Not only did Kitty Dukakis suffer from depression, but she was also dependent on amphetamine pills—"uppers"—and alcohol (Dukakis & Tye, 2006). Some researchers investigate differences between people who suffer from both depression and substance abuse (as Dukakis did) and those who suffer only depression. Researchers have also examined the effect of substance abuse on the course of depression (Agosti & Levin, 2006).

Without a classification system for psychological disorders, the problems that Pete Wentz, Carolina Reston, and Keith Urban appear to have suffered from—bipolar disorder, anorexia nervosa, and substance abuse, respectively—would be nameless. Among other purposes, a classification system allows clinicians to diagnose and treat symptoms more effectively, allows patients to know that they are not alone in their experiences, and helps researchers to investigate the factors that contribute to psychological disorders and to evaluate treatments.

Steve Liss/Time Life Pictures/Getty Images

Kitty Dukakis became intimately familiar with her symptoms of depression: "It is June 20, 2001, Michael's and my 38th wedding anniversary. It also is the end of my fourth month of depression, my crisis period. I'm normally a person with enormous enthusiasm for and interest in the world. All that is just missing now. Fun or enjoyment are things I cannot even imagine. I don't speak to my kids on the phone, or to my sister" (Dukakis & Tye, 2006).

Other researchers have examined how best to treat people with both substance abuse and depression, compared to those with only substance abuse (Dodge, Sindelar, & Sinha, 2005; Torrens et al., 2005). Such comparisons are possible only because the diagnoses are part of a classification system.

- *A diagnosis can indicate that an individual is in need of attention (including treatment), support, or benefits.* For example, children diagnosed with a learning disorder may receive special accommodations or services at school. For some adults, a diagnosis may allow them to have special accommodations at home or work or to receive certain services paid for by their health insurance plan or by government programs. For some people involved in criminal justice proceedings, a diagnosis of a psychological disorder, such as schizophrenia, may make the difference between being sent to a mental health facility and going to prison or jail.
- *Some people find great relief in learning that they are not alone in having particular problems* (see Case 3.1). People may derive a measure of comfort from merely being given a label for their problems—knowing not only that there is a term for their disturbing thoughts, feelings, and behaviors, but also that they are not the only one with the specific difficulties. Moreover, once they have a name for the symptoms they are experiencing, they can learn more about the disorder and treatments for it.

CASE 3.1 ► FROM THE OUTSIDE: On Being Diagnosed with a Disorder

Sally, an articulate and dynamic 46-year-old woman, came to share her experiences with our psychiatry class. For much of her adult life, she had suffered from insomnia, panic attacks, and intense fear. Then, six years ago, a nightmare triggered memories of childhood sexual abuse and she was finally diagnosed with posttraumatic stress disorder.

Being diagnosed, she told us, was an intense relief.

“All those years, I thought I was just crazy,” she said. “My whole family used to call me the crazy one. Once, my brother called my mom and asked, ‘So, how’s my crazy sister?’ But all of a sudden I wasn’t crazy any more. It had a name. It had a real reason. I could finally understand why I felt the way I did,” she said.”

(Rothman, 1995)

A Cautionary Note About Diagnosis

Having a classification system for mental illness has many advantages, but assigning the appropriate diagnosis can be a challenge. For example, clinicians may be biased to make—or not make—particular diagnoses for certain groups of people. Patients, once diagnosed with a disorder, may be stigmatized because of it. Relatives and friends, as well as patients, often struggle to answer this question: Does having a psychological disorder exempt patients from being responsible for their behavior? Let’s examine the possibilities of bias and stigma in more detail.

Diagnostic Bias

A **diagnostic bias** is a systematic error in diagnosis (Meehl, 1960). Such a bias can cause groups of people to receive a particular diagnosis disproportionately, on the basis of an unrelated factor such as sex, race, or age (Kunen et al., 2005). Studies of diagnostic bias show, for example, that in the United States, black patients are more likely than white patients to be diagnosed with schizophrenia instead of a mood disorder (Abreu, 1999; Garb, 1997; Neighbors et al., 2003; Trierweiler et al., 2005). Black patients are also prescribed higher doses of medication than are white patients (Strakowski, Shelton, & Kolbrener, 1993).

When the mental health clinician is not familiar with the social norms of the patient’s cultural background, the clinician may misinterpret certain behaviors as

Diagnostic bias

A systematic error in diagnosis.

pathological, and thus be more likely to diagnose a psychological disorder. So, for instance, the clinician might view a Caribbean immigrant family's closeness as "overinvolvement" rather than as normal for that culture.

Other groups, such as low-income Mexican Americans, may have their mental illnesses under-diagnosed (only a percentage of cases are diagnosed) (Schmaling & Hernandez, 2005). Part of the explanation for the under-diagnosis may be that the constellation of symptoms experienced by some Mexican Americans does not fit within the classification system currently used in North America; another part of the explanation may be language differences between patient and clinician that make accurate assessment difficult (Kaplan, 2007; Villaseñor & Waitzkin, 1999).

Diagnosis as a Stigmatizing Label

When someone has a psychological disorder, the diagnosis may be seen as a stigmatizing label that influences how other people—including the mental health clinician—view and treat the person. It may even change how a diagnosed person behaves and feels about himself or herself (Eriksen & Kress, 2005). Such labels can lead some people with a psychological disorder to blame themselves and try to hide their problems (Corrigan & Watson, 2001; Wahl, 1999). Feelings of shame may even lead them to refrain from obtaining treatment (U.S. Department of Health and Human Services, 1999).

Great strides have been made toward destigmatizing mental illness, although there is still a way to go. In 2006, actor Tom Cruise said about actor Brooke Shield's postpartum depression, "When you talk about postpartum, you can take people today, women, and what you do is you use vitamins. There is a hormonal thing that is going on, scientifically, you can prove that. But when you talk about emotional, chemical imbalances in people, there is no science behind that" (Grove, 2005). However, to the contrary, clinicians and researchers do in fact have scientific evidence that chemical imbalances can be involved in a psychological disorder. And, fortunately, many people challenged Cruise's statements by providing facts, leading to greater awareness of postpartum depression. One organization devoted to confronting the stigma of mental illness is the National Alliance for the Mentally Ill (nami.org), which has a network of advocates—called StigmaBusters—who combat incorrect and insensitive portrayals of mental illness in the media.

The National Alliance for the Mentally Ill protested the airing of a television show, *Crumbs*, and its portrayal of the lead character, Mother Crumb, who was hospitalized with a "nervous breakdown." When her mental illness led to violent behavior, audience laughter followed. The show both trivialized mental illness and reinforced stereotypes of the mentally ill.

Reliability and Validity in Classification Systems

Classification systems are most useful when they are reliable and valid. If a classification system yields consistent results over time, it is **reliable**. To understand what constitutes a reliable classification system, imagine the following scenario about Rose Mary Walls: Suppose she decided to see a mental health clinician because she was sleeping a lot, crying every day, and losing weight. Further, she consented to have her interview with the clinician filmed for other clinicians to watch. Would every clinician who watched the videoclip hear Rose Mary's words and see her behavior in the same way? Would every clinician diagnose her as having the same disorder? If so, then the classification system they used would be deemed reliable. But suppose that various clinicians came up with different diagnoses or were divided about whether Rose Mary even had a disorder. They might make different judgments about how her behaviors or symptoms fit into the classification system. That is, they might interpret the same behaviors and characteristics differently. For instance, some clinicians might interpret Rose Mary's experiences and behaviors as appropriate to the situation—as understandable given the regular disruptions to her social and family life. If there were significant differences of opinion about her diagnosis among the clinicians, the classification system they used probably is not reliable.

Reliable

Classification systems (or measures) that consistently produce the same results.

Problems concerning reliability in diagnosis can occur when:

- *the criteria for disorders are unclear*, and thus require the clinician to use considerable judgment about whether symptoms meet the criteria; or
- *there is significant overlap among disorders*, which can then make it difficult to distinguish among them.

However, just because clinicians agree on a diagnosis doesn't mean that the diagnosis is correct! For example, in the past, there was considerable agreement about the role of the devil in producing mental disorders, but we now know that this isn't a valid explanation. Science is not a popularity contest; what the majority of observers believe at any particular point in time is not necessarily correct. Thus, another requirement for any classification system is that it needs to be **valid**—the categories must characterize what they are supposed to be classifying. Each disorder should have a unique set of criteria that are necessary for the diagnosis to be made.

The reliability and validity of classification systems are important in part because such systems are often used to study the etiology of a psychological disorder, its **prognosis** (the likely course and outcome of the disorder), and whether particular treatments will be effective. In order to use a classification system in this way, however, the **prevalence** of each disorder—the number of people who have the disorder in a given period of time—must be large enough that researchers are likely to encounter people with the disorder. (A related term is *incidence*, which refers to the total number of new cases of a disorder that are identified in a given time period.)

In addition, to be valid, the criteria must not be too restrictive or too broad. If the criteria for diagnosing a particular disorder are so restrictive that the disorder's prevalence is very low, not much will be discovered about its course or the most effective treatments. On the other hand, if the criteria for a disorder are so broad that the disorder is very common, the criteria may reflect a set of different (but perhaps related) problems or even include aspects of normal—not abnormal—psychological functioning; in either case, the classification is not of much use (Kutchins & Kirk, 1997).

In sum, a classification system should be as reliable and valid as possible in order to be useful for patients, clinicians, and researchers. Next, we'll examine the most commonly used classification system for psychological disorders—the system in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM).

The Diagnostic and Statistical Manual of Mental Disorders

Suppose that child welfare officials had spoken with Rex and Rose Mary Walls and required that the parents be evaluated by mental health professionals. How would a mental health clinician go about determining whether or not either of them had a disorder? What classification system would the clinician probably use? The classification system that most clinicians use in the United States is found in the *Diagnostic and Statistical Manual of Mental Disorders*, which is currently in its fourth edition. This guide, published by the American Psychiatric Association (2000), describes the characteristics of many psychological disorders and identifies *criteria*—the kinds, number, and duration of relevant symptoms—for diagnosing each disorder. This classification system is *categorical*—someone either has a disorder or does not.

A different classification system, described in the *International Classification of Diseases* (ICD), is used in some other parts of the world. The World Health Organization (WHO) develops the ICD, which is currently in its tenth edition. The primary purpose of the ICD is to provide a framework for collecting health statistics worldwide. Unlike the DSM, however, the ICD includes many diseases and

Valid

Classification systems (or measures) that actually characterize what they are supposed to characterize.

Prognosis

The likely course and outcome of a disorder.

Prevalence

The number of people who have a disorder in a given period of time.

disorders, not just psychological disorders. In fact, until the sixth edition, the ICD only classified causes of death. With the sixth edition, the editors added diseases, of which mental disorders were one type. Current versions of the mental disorders sections of the ICD and the DSM have been revised to overlap substantially. Research on prevalence that uses one classification system is now applicable to the other system.

The Evolution of DSM

When the original version of the DSM was published in 1952, it was the first manual to address the needs of clinicians rather than researchers (Beutler & Malik, 2002). At that time, psychodynamic theory was popular, and the DSM strongly favored the psychodynamic approach in its classifications. For example, it organized mental illness according to different types of conflicts among the id, ego, superego, and reality, as well as different patterns of defense mechanisms employed (American Psychiatric Association, 1952). The second edition of the DSM, published in 1968, had only minor modifications. The first two editions were criticized for problems with reliability and validity, which arose in part because their classifications relied on psychodynamic theory. Clinicians had to draw many inferences about the specific nature of patients' problems, including the specific unconscious conflicts that motivated patients' behavior.

The authors of the third edition (DSM-III), published in 1980, set out to create a classification system that had better reliability and validity. Unlike the previous editions, DSM-III:

1. did not rest on the psychodynamic theory of psychopathology (or on any other theory);
2. focused more on what can be observed than on what can be inferred;
3. listed explicit criteria for each disorder and began to use available research results to develop those criteria; and
4. included a system for clinicians and researchers to record diagnoses as well as additional information—such as related medical history—that may affect diagnosis, prognosis, and treatment.

Some of the criteria in DSM-III were not clear, however, and various inconsistencies were identified. So, in 1987, a revised version was published. DSM-III-R (R for “Revised”) provided more explicit criteria than did previous editions, which meant that it had greater reliability (Malik & Beutler, 2002). Researchers in different hospitals could collect information about prevalence, etiological factors, course, or treatment from patients with a particular disorder and be reasonably certain that they all were studying the same disorder. However, this research revealed certain limitations of DSM-III-R, including continuing problems with validity (Malik & Beutler, 2002). For instance, criteria were too restrictive for some disorders; thus, even though some individuals, such as those with preoccupations of physical illness, were clearly distressed or impaired, their symptoms did not meet enough of the criteria for a diagnosis (Rief et al., 1996; Wise & Birket-Smith, 2002).

The Multiaxial System of DSM-IV-TR

The weaknesses of DSM-III-R led to DSM-IV, published in 1994, which specified new disorders and revised the criteria for some of the disorders included in DSM-III-R. In 2000, the American Psychiatric Association published an expanded version of DSM-IV that included more current information about each disorder, such as new information about prevalence, course, issues related to gender and cultural factors, and **comorbidity**—the presence of more than one disorder at the same time in a given patient. This revised edition is called DSM-IV-TR, where *TR* stands for “Text Revision.” The list of disorders and almost all of

Comorbidity

The presence of more than one disorder at the same time in a given patient.

Table 3.1 ▶ The 17 Categories of Psychological Disorders in DSM-IV-TR

Adjustment Disorders
 Anxiety Disorders
 Delirium, Dementia, and Amnesic and Other Cognitive Disorders
 Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence
 Dissociative Disorders
 Eating Disorders
 Factitious Disorders
 Impulse-Control Disorders
 Mental Disorders Due to a General Medical Condition
 Mood Disorders
 Other Conditions That May Be a Focus of Clinical Attention
 Personality Disorders
 Schizophrenia and Other Psychotic Disorders
 Sexual and Gender Identity Disorders
 Sleep Disorders
 Somatoform Disorders
 Substance-Related Disorders

the criteria were not changed, but the text discussion of the disorders was revised. DSM-IV and DSM-IV-TR define 17 major categories of psychological problems, listed in Table 3.1, and nearly 300 specific mental disorders—almost triple the number in DSM-III. As work progresses on the fifth edition of DSM, some researchers and clinicians support the inclusion of additional disorders, such as “Internet addiction” (Block, 2008) and “night eating syndrome” (Stunkard, Allison, & Lundgren, 2008).

DSM-III introduced five *axes* (which is why it is called *multiaxial*), each of which delineates specific kinds of information to be noted about a patient. These axes are still included in DSM-IV-TR (see Table 3.2), and they may be used for diagnosing a patient, for planning treatment, for prognosis, or for research purposes. In addition to these axes, an appendix in DSM-IV-TR outlines aspects of the cultural context that clinicians should consider when making a diagnosis for a particular patient.

The first two axes specify the diagnosed disorders. Disorders listed on *Axis I* include most of the disorders in DSM-IV-TR and in this book, such as social phobia and bulimia nervosa. If an individual has comorbid *Axis I* disorders, all of the disorders are listed. For instance, if an individual has both social phobia and bulimia nervosa, both disorders would be listed on *Axis I*.

Disorders listed on *Axis II* include mental retardation and *personality disorders*—personality traits that are so inflexible and self-defeating that they impair functioning (discussed in detail in Chapter 13). The authors of DSM-III’s multiaxial system believed that the presence of mental retardation or a personality disorder in a patient could significantly affect the expression of symptoms of other disorders—those on *Axis I*. Having a separate axis—*Axis II*—to specify such disorders ensures that these types of symptoms receive special attention. For example, suppose that a man who has moderate mental retardation lately seems to be “not himself”—he’s been crying often, but when asked why, he says he doesn’t know. His mental retardation makes it difficult for him to express himself well. The clinician diagnosing the man would need to determine how his mental retardation affects the way he expresses symptoms of a comorbid psychological disorder, such as depression or anxiety. Moreover, the presence of mental retardation may indicate that certain treatments would be more appropriate than others.

On *Axis III*, mental health clinicians or researchers list any physical disorders or disabilities that might be relevant to the disorders on *Axis I* or *II*. For instance, an elderly woman with poor eyesight who recently suffered a hip fracture after a fall may now feel so anxious about leaving home that she has *panic attacks*—episodes of extreme fear, terror, or dread. In order to diagnose and treat this woman’s problems appropriately, a clinician would need to know about both her visual problems and her recent hip fracture; both medical problems would be noted on *Axis III*.

The first three axes focus on current psychological and medical disorders. *Axis IV* focuses on the wider context of the disorder: social and environmental problems that could affect the diagnosis, treatment, and prognosis of a disorder. Knowing that a depressed patient’s mother recently died, for instance, may influence both the diagnosis and recommended treatment, if any. Social problems that affect a person’s psychological state are often called *psychosocial* problems. Such psychosocial and environmental problems include (American Psychiatric Association, 2000, pp. 31–32):

1. problems with the person’s primary support group (e.g., marital conflict or divorce, or some type of maltreatment);
2. problems with the social environment (e.g., the death of a friend or discrimination);
3. educational problems (e.g., academic problems or difficulties with a teacher);

4. occupational problems (e.g., unemployment or stressful working conditions);
5. housing problems (e.g., homelessness or an unsafe neighborhood);
6. economic problems (e.g., extreme poverty);
7. problems with access to health care (e.g., inadequate health insurance or lack of transportation to health care facilities); and
8. legal difficulties (e.g., being arrested or being a victim of a crime).

Axis V requires the clinician or researcher to provide a numerical estimate (between 1 and 100) of the patient's global functioning within the past year. As shown in Table 3.3, the number indicates the highest level of functioning the patient has achieved in his or her work, relationships, and leisure time or the patient's current level of functioning. This information can be used to plan treatment and estimate the level of functioning likely to be attained after treatment.

Consider a 25-year-old woman, Lia, who has suffered from delusions and hallucinations from time to time over the last 5 years and has been diagnosed with schizophrenia. Lia was briefly hospitalized because her hallucinations had gotten much worse, but she's now out of the hospital and stable. A clinician would want to know how well Lia had been doing during the past year as a guide to what level of functioning might be possible for her. If her symptoms had been relatively under control and she had been attending college part-time, the prognosis would probably be better than if she had been living at home, not doing anything during the day, and not always able to care for herself. Similarly, if Lia had been able to attend college, treatment might focus, in part, on identifying factors associated with the onset of more severe symptoms and on developing coping strategies and social support to help her resume her higher level of functioning. Had she previously been unable to care for herself, treatment would focus on helping Lia develop basic self-care abilities—maintaining hygiene, preparing meals—and creating some type of daily structure to organize her time.

Table 3.3 ▶ Axis V: Global Assessment of Functioning Scale

91–100	Superior functioning in a wide range of activities, life's problems never seem to get out of hand, is sought out by others because of his or her many positive qualities. No symptoms.
81–90	Absent or minimal symptoms (e.g., mild anxiety before an exam), good functioning in all areas, interested and involved in a wide range of activities, socially effective, generally satisfied with life, no more than everyday problems or concerns (e.g., an occasional argument with family members).
71–80	If symptoms are present, they are transient and expectable reactions to psychosocial stressors (e.g., difficulty concentrating after family argument); no more than slight impairment in social, occupational, or school functioning (e.g., temporarily falling behind in schoolwork).
61–70	Some mild symptoms (e.g., depressed mood and mild insomnia) OR some difficulty in social, occupational, or school functioning (e.g., occasional truancy or theft within the household), but generally functioning pretty well, has some meaningful interpersonal relationships.
51–60	Moderate symptoms (e.g., flat affect and circumstantial speech, occasional panic attacks) OR moderate difficulty in social, occupational, or school functioning (e.g., few friends, conflicts with peers or coworkers).
41–50	Severe symptoms (e.g., suicidal ideation, severe obsessional rituals, frequent shoplifting) OR any serious impairment in social, occupational, or school functioning (e.g., no friends, unable to keep a job).
31–40	Some impairment in reality testing or communication (e.g., speech is at times illogical, obscure, or irrelevant) OR major impairment in several areas, such as work or school, family relations, judgment, thinking, or mood (e.g., depressed man avoids friends, neglects family, and is unable to work; child frequently beats up younger children, is defiant at home, and is failing at school).
21–30	Behavior is considerably influenced by delusions or hallucinations OR serious impairment in communication or judgment (e.g., sometimes incoherent, acts grossly inappropriately, suicidal preoccupation) OR inability to function in almost all areas (e.g., stays in bed all day; no job, home, or friends).
11–20	Some danger of hurting self or others (e.g., suicide attempts without clear expectation of death, frequently violent, manic excitement) OR occasionally fails to maintain minimal personal hygiene (e.g., smears feces) OR gross impairment in communication (e.g., largely incoherent or mute).
1–10	Persistent danger of severely hurting self or others (e.g., recurrent violence) OR persistent inability to maintain minimal personal hygiene OR serious suicidal act with clear expectation of death.
0	Inadequate information.

The Global Assessment of Functioning Scale asks the clinician to “consider psychological, social, and occupational functioning on a hypothetical continuum of mental health—illness. Do not include impairment in functioning due to physical or environmental limitations” (American Psychiatric Association, 2000, p. 34).

Criticisms of DSM-IV-TR

Most mental health professionals agree that DSM-IV-TR is an improvement over previous editions, but its classification system has been criticized on a number of grounds. To understand the criticisms, we will focus on the DSM-IV-TR criteria

Table 3.4 ▶ DSM-IV-TR Diagnostic Criteria for Schizophrenia

A. Characteristic symptoms: Two (or more) of the following, with each being present for a significant portion of time during a 1-month period:

- (1) delusions
- (2) hallucinations
- (3) disorganized speech (evidenced by sentences that make no sense because words are scrambled and the thoughts appear disconnected).
- (4) grossly disorganized behavior (including difficulty with daily tasks such as organizing a meal or maintaining proper hygiene).

Note: The first four symptoms are often referred to as *positive* symptoms, because they suggest the *presence* of an excess or distortion of normal functions.

- (5) negative symptoms (which indicate an absence of normal functions), such as a failure to express or respond to emotion; slow, empty replies to questions; or an inability to initiate goal-directed behavior.

Note: Only one Criterion A symptom is required if delusions are bizarre or hallucinations consist of a voice keeping up a running commentary on the person's behavior or thoughts, or two or more voices conversing with each other.

B. Social/occupational dysfunction: Since the disturbance began, one or more major areas of functioning such as work, interpersonal relations, or self-care are *markedly* below the level achieved before the disturbance appeared.

C. Duration: Continuous signs of the disturbance persist for at least 6 months, with at least 1 month of symptoms that meet Criterion A.

Source: Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Text Revision, Fourth Edition, (Copyright 2000) American Psychiatric Association.

for a diagnosis of schizophrenia as an example (see Table 3.4); this disorder is discussed in more detail in Chapter 12. The criticisms raised in this discussion apply to most DSM-IV-TR disorders. Let's examine those criticisms in detail.

Determining Clinical Significance

Consider symptoms A3 and A4 in Table 3.4: disorganized speech and grossly disorganized behavior. DSM-IV-TR instructs the clinician to determine what constitutes *clinically significant* disorganized speech or behavior. Part of the problem is that this decision, to a certain extent, is subjective. Similarly, in Criterion B, dysfunction must be *markedly* below the person's previous level of functioning. But DSM-IV-TR does not specify what, exactly, *markedly* means (Caplan, 1995; Frances, First, & Pincus, 1995). Not all professionals would consider the same patient's dysfunction marked *enough* to qualify as a symptom of schizophrenia. These problems are complicated further if the clinician relies on the patient's description of his or her previous level of functioning; the patient's view of the past may be clouded by the present symptoms.

In a similar vein, consider the category of disorders known as *adjustment disorders* (see Table 3.1): These disorders are characterized by a response to an identifiable stressor that is *in excess of what would normally be expected*. The clinician must determine whether an

individual's response is excessive. However, different people have different coping styles, and what seems to one clinician like an excessive response may be deemed normal by another clinician.

Disorders as Categories, Not Continua

DSM-IV-TR is structured so that someone either has or does not have a given disorder. It's analogous to the old adage about pregnancy: A woman can't be a little bit pregnant—she either is or isn't pregnant. But critics argue that many disorders may exist along continua (continuous gradations), meaning that patients can have different degrees of a disorder (Kendell & Jablensky, 2003).

Some psychologists propose that when the fifth edition of DSM is developed, each disorder should be classified on a continuum, where the number or severity of symptoms indicates the degree of severity of the disorder (Malik & Beutler, 2002; Westen et al., 2002). Subsequent editions of DSM may include a way to diagnose disorders along a continuum in addition to a version of the current categorical system (First, 2006). If disorders were specified along a continuum, planning appropriate goals and treatments would be easier, and prognoses might be more accurate.

Consider, for example, two young men who have had the diagnosis of schizophrenia for 5 years. Aaron has been living with roommates and attending college part-time; Max is living at home, continues to hallucinate and have delusions, and cannot hold down a volunteer job. Over the holidays, both men's symptoms got worse and both were hospitalized briefly. Since being discharged from the hospital, Aaron has only mild symptoms, but Max still can't function independently even though he no longer needs to be in the hospital. The categorical diagnosis of schizophrenia lumps both of these patients together, but the intensity of their symptoms suggests that clinicians should have different expectations, goals, treatments, and prognoses for them. As shown in Figure 3.1, on a dimensional scale, one of them is likely to be diagnosed with mild schizophrenia, whereas the other is likely to be diagnosed with severe schizophrenia.

Similarly, consider Allie and Lupe, both of whom are afraid of bugs and spiders. Lupe mildly dislikes insects and avoids them whenever possible, but she doesn't freak out when she sees a spider; Lupe's fear of bugs doesn't reach the cutoff for a disorder (it doesn't significantly impair her functioning or cause her excessive distress). Allie, in contrast, lives in fear of spiders and refuses to open her windows because she worries that spiders might invade her apartment. As a result, the air is stifling hot in her apartment during the summer. Allie's fear and avoidance of spiders are probably severe enough to be considered a disorder.

Heterogeneous Groups Have the Same Disorder

For many DSM-IV-TR disorders, including schizophrenia, a person needs to have only some of the symptoms in order to be diagnosed with the disorder. For example, under Criterion A in Table 3.4, a person needs to have only two out of the five symptoms. This means that some people with schizophrenia may have delusions and hallucinations, whereas others may have disorganized speech and disorganized behavior, but *no* delusions or hallucinations. Moreover, still other people classified as having schizophrenia may have negative symptoms and delusions, but not exhibit disorganized behavior or experience hallucinations. Taken together, these three groups of people with schizophrenia are *heterogeneous*—they are different from each other.

If the different combinations of symptoms do in fact reflect a single underlying disorder (in other words, if the category is valid), this is not a problem. But it is possible—and many researchers believe it is likely (Messias & Kirkpatrick, 2001; Tek et al., 2001)—that people who have different combinations of symptoms have distinct types of schizophrenia, perhaps with different causes and prognoses. If so, then it is an error to group them together. And this may be true for most disorders in DSM-IV-TR. People with different combinations of symptoms may have developed the disorder in different ways, and different treatments might be effective. Thus, the DSM-IV-TR diagnostic system may obscure important differences among types of a given mental disorder (Malik & Beutler, 2002).

Symptoms Are Weighted Equally

In the DSM-IV-TR system, the diagnostic criteria for a given disorder, in essence, produce a checklist; each criterion (and the symptoms reflected in it, such as the five symptoms in Criterion A in Table 3.4) is generally weighted equally (Malik & Beutler, 2002). But each symptom in the list of criteria for a given disorder may not be equally important for diagnosis. For instance, patients with schizophrenia who primarily have delusions or hallucinations are generally less impaired and have a better prognosis than those who primarily have negative symptoms such as flat affect (diminished emotional expression) or difficulty initiating goal-directed behavior (McGlashan & Fenton, 1993).

Duration Criteria Are Arbitrary

Each set of criteria for a disorder specifies a minimum amount of time that symptoms must be present for a patient to qualify for that diagnosis (see Criterion C in Table 3.4). However, the specification of a particular duration, such as that noted for bulimia nervosa (which requires that the symptoms be present for at least 3 months), is often arbitrary and not supported by research (Sullivan, Bulik, & Kendler, 1998).

The requirement for a specific duration also means that someone's diagnostic status can change literally overnight. For instance, for the diagnosis of social phobia, symptoms of significant fear in social situations must have persisted for at

Figure 3.1

3.1 ▶ A Disorder as on a Continuum If a disorder such as schizophrenia is best characterized along a continuum, then two people, Aaron and Max, diagnosed with schizophrenia but with different severity or numbers of symptoms, would fall at different points on the continuum. Aaron has fewer symptoms and is able to function better than Max. According to DSM-IV-TR, they both have the same disorder. However, their illnesses have different courses and prognoses and will likely require different types of treatment. None of this information is captured by the categorical diagnostic system of DSM-IV-TR.

least 6 months. Someone who had these symptoms for 5 months and 29 days would not be diagnosed with the disorder, but if the symptoms persisted another day, he or she would be so diagnosed.

Some Sets of Criteria Are Too Restrictive

Each category of disorders in DSM-IV-TR includes a *not otherwise specified* (NOS) diagnosis (American Psychiatric Association, 2000)—a nonspecific diagnosis to be used when a person's symptoms do not meet all the necessary criteria for the disorder that is the best fit, but the individual is significantly distressed and impaired. For instance, someone who had some—but not enough—of the symptoms to meet the criteria for schizophrenia or another psychotic disorder would be diagnosed as having *psychotic disorder NOS*; this would be the case, for example, for someone with only negative symptoms of schizophrenia (Criterion A5 in Table 3.4).

With some disorders, though, the criteria are so restrictive that *most* of the distressed and impaired patients with appropriate symptoms don't meet all the relevant criteria to be diagnosed with that disorder; this is true for people with eating disorders (Sloan, Mizes, & Epstein, 2005): Most people with an eating disorder are diagnosed with the more general (and less reliable) *eating disorder NOS*, rather than with *bulimia nervosa* or *anorexia nervosa*, the two diagnoses in the eating disorders category. The criteria for bulimia and anorexia are sufficiently restrictive that most people with eating-related problems who have significant distress, dysfunction, or risk of harm have symptoms that fall short of the criteria. Those diagnosed with *eating disorder NOS* are a very heterogeneous group of people, who have varying problems associated with food and eating.

When NOS diagnoses occur frequently for a particular category of disorders, as is the case with eating disorders, the criteria for the disorders may not meaningfully capture the important elements needed for diagnosis—and hence the set of criteria should be reevaluated.

Psychological Disorders are Created to Ensure Payment

With each edition of DSM, the number of disorders has increased, reaching almost 300 with DSM-IV. Does this mean that more types of mental disorders have been discovered and classified? Not necessarily. This increase may, in part, reflect economic pressures in the mental health care industry (Eriksen & Kress, 2005). Today, in order for a mental health facility or provider to be paid or a patient to be reimbursed by health insurance companies, the patient must have symptoms that meet a DSM-IV-TR diagnosis. Prior to DSM-III-R, this requirement for payment did not generally exist. The more disorders that are included in a new edition of DSM, then, the more likely it is that a patient's treatment will be paid for or reimbursed by health insurance companies. But this does not imply that all of the disorders are valid from a scientific perspective.

Medical Illnesses are Made into Psychological Disorders

The DSM is beginning to include medical disorders, which are not clearly *psychological* disorders (Eriksen & Kress, 2005). For example, *breathing-related sleep disorder*, which is included in DSM-IV-TR, is caused in part by an obstruction of the breathing passage, a medical condition. No research evidence or medical discoveries warranted the addition of this sleep disorders to Axis I of the DSM. Rather, the decision was made by a small number of psychiatrists on the DSM committee in order to ensure that treatment of this sleep disorder by mental health clinicians would be paid for by health insurance companies; treatment by mental health clinicians for disorders that are not included in the DSM is less likely to be paid for by most health insurance plans (Houts, 2002).

However, the push to include medical conditions in DSM is not entirely based on financial considerations: Clinicians have found that treatments developed for some psychological disorders can also be used to treat some medical disorders successfully (Deckersbach et al., 2006). For example, a number of psychological treatments

can help reduce symptoms of irritable bowel syndrome, a medical disorder marked by intestinal cramping, bloating, and diarrhea (Blanchard et al., 2006; Whitehead, 2006). Even so, this does not justify including a medical disorder in the DSM.

Social Factors are Deemphasized

Perhaps because DSM-IV-TR does not generally address etiological factors (the causes of a disorder), it does not explicitly recognize social factors that *contribute* to disorders (as opposed to the listing of current psychosocial problems on Axis IV). DSM-IV-TR states that its diagnoses are not supposed to apply to conflicts between an individual and society, but rather to conflicts within an individual. However, this distinction is often difficult to make (Caplan, 1995). For instance, people can become depressed in response to a variety of social stressors: after losing their jobs, after they are exposed to systematic discrimination, after emigrating from their native country, or after experiencing other social and societal conflicts.

Comorbidity is Common

About half of the people who are diagnosed with a DSM-IV-TR disorder have at least one additional disorder; that is, they exhibit comorbidity (Kessler et al., 2005). This raises the question of whether the disorders in DSM-IV-TR describe unique clusters of symptoms. For instance, half of the people who are clinically depressed—that is, whose depression meets the criteria for the DSM-IV-TR disorder *major depressive disorder*—also have an anxiety disorder (Kessler et al., 2003). Such a high rate of comorbidity suggests that, for a significant number of people, the two DSM-IV-TR disorders may represent different facets of the same underlying problem. This possibility raises questions about validity and makes DSM-IV-TR diagnoses less useful to clinicians and researchers.

Overlooks Commonalities Across Diagnostic Categories

The structure of DSM-IV-TR makes it difficult for researchers to identify commonalities that underlie disorders across the 17 categories. Such commonalities arise either when particular disorders are frequently comorbid—as is common with depression and anxiety—or when various disorders have some symptoms in common. In either case, commonly comorbid disorders may be better classified as different expressions of the same core problem, rather than the way DSM-IV-TR does—as completely separate disorders.

For example, many emotional and behavioral problems can be categorized as hinging on either overcontrol or undercontrol; such problems often begin in childhood and persist into adulthood. Problems that involve overcontrol are referred to as *internalizing* problems because they are largely characterized by the internal experiences associated with them; examples include depression and various types of anxiety. Problems that involve undercontrol are referred to as *externalizing* problems because they are largely characterized by their effects on others and on the environment; examples include aggression and disruptive behaviors, such as occur in attention-deficit/hyperactivity disorder and delinquency. Not all emotional or behavioral problems fit into these categories, however, and an “other” category was created to include eating disorders and learning disorders (Achenbach, McConaughy, & Howell, 1987; Kazdin & Weisz, 1998). But DSM-IV-TR doesn’t provide any way to classify or group disorders that involve internalizing or externalizing problems, making it more challenging for researchers to identify commonalities.

Although the criticisms of DSM-IV-TR have merit, the clinical chapters of this book (Chapters 6–15) are generally organized according to DSM-IV-TR categories and criteria. DSM-IV-TR is by far the most widely used classification system for diagnosing psychological disorders, and it will no doubt provide the foundation for a revised edition in the future.

Joe Raedle/Getty Images

One criticism of DSM-IV-TR is that social factors that contribute to psychological disorders—such as being laid off from work—are not incorporated into the diagnosis (Caplan, 1995).

The People Who Diagnose Psychological Disorders

Who, exactly, are the mental health professionals who might diagnose Rex or Rose Mary Walls, or anyone else who might be suffering from a psychological disorder? As you will see, there are different types of mental health professionals, each with a different type of training. The type of training can influence the kinds of information that clinicians pay particular attention to, what they perceive, and how they interpret the information. However, regardless of the type of training and educational degrees they receive, all mental health professionals must be licensed in the state in which they practice (or board-certified in the case of psychiatrists); licensure indicates that they have been appropriately trained to diagnose and treat mental disorders. However, there are no laws that prevent people who have not been trained in approved ways—and therefore are not licensed by the state—from calling themselves psychotherapists.

Clinical Psychologists and Counseling Psychologists

A **clinical psychologist** generally has a doctoral degree, either a Ph.D. (doctor of philosophy) or a Psy.D. (doctor of psychology), that is awarded only after several years of coursework (on mental processes, learning theory, psychological testing, the assessment of psychological disorders, psychological treatments, and ethics) and several years of treating patients while receiving supervision from experienced clinicians. People training to be clinical psychologists also take other courses that may include neuropsychology and psychopharmacology. In addition, clinical psychologists with a Ph.D. will have completed a *dissertation*—a major, independent research project. Programs that award a Psy.D. in clinical psychology place less emphasis on research.

Clinical neuropsychologists are a particular type of clinical psychologist. Clinical neuropsychologists concentrate on characterizing the effects of brain damage and neurological diseases (such as Alzheimer's disease) on thoughts (that is, mental processes and mental contents), feelings (affect), and behavior. Sometimes, they help design and conduct rehabilitation programs for patients with brain damage or neurological disease.

Counseling psychologists might have a Ph.D. from a psychology program that focuses on counseling or might have an Ed.D. (doctor of education) degree from a school of education. Their training is similar to that of clinical psychologists except that counseling psychologists tend to have more training in vocational testing, career guidance, and multicultural issues, and they generally don't receive training in neuropsychology. Counseling psychologists also tend to work with healthier people, whereas clinical psychologists tend to have more training in psychopathology and often work with people who have more severe problems (Cobb et al., 2004; Norcross et al., 1998). The distinction between the two types of psychologists, however, is less clear-cut than in the past, and both types may perform similar work in similar settings.

Clinical psychologists and counseling psychologists are trained to perform research on the nature, diagnosis, and treatment of mental illness. They also both provide *psychotherapy*, which involves helping patients better cope with difficult experiences, thoughts, feelings, and behavior. Both types of psychologists also learn how to administer and interpret psychological tests in order to diagnose and treat psychological problems and disorders more effectively.

Psychiatrists, Psychiatric Nurses, and General Practitioners

Someone with an M.D. (doctor of medicine) degree can choose to receive further training in a residency that focuses on mental disorders, becoming a **psychiatrist**. A psychiatrist is qualified to prescribe medications; psychologists in the United States, except for appropriately trained psychologists in New Mexico and Louisiana, currently may not prescribe medications (other states are considering allowing appropriately trained psychologists to prescribe). But psychiatrists usually have not been taught how to interpret and understand psychological tests and have not

Clinical psychologist

A mental health professional who has a doctoral degree that requires several years of related coursework and several years of treating patients while receiving supervision from experienced clinicians.

Counseling psychologist

A mental health professional who has either a Ph.D. degree from a psychology program that focuses on counseling or an Ed.D. degree from a school of education.

Psychiatrist

A mental health professional who has an M.D. degree and has completed a residency that focuses on mental disorders.

been required to acquire detailed knowledge of research methods used in the field of psychopathology.

Psychiatric nurses have an M.S.N. (master of science in nursing) degree, plus a C.S. (clinical specialization) certificate in psychiatric nursing; a psychiatric nurse may also be certified as a psychiatric nurse practitioner (N.P.). Psychiatric nurses normally work in a hospital or clinic to provide psychotherapy; in these settings, they work closely with physicians to administer and monitor patient medications. Psychiatric nurses are also qualified to provide psychotherapy in private practice and are permitted in some states to monitor and prescribe medications independently (Haber et al., 2003).

Although not considered a mental health professional, a *general practitioner* (GP), or family doctor—the doctor you may see once a year for a checkup—may inquire about psychological symptoms, may diagnose a psychological disorder, and may recommend to patients that they see a mental health professional. Responding to pressure to reduce insurance companies' medical costs, general practitioners frequently prescribe medication for some psychological disorders. However, studies have found that treatment with medication is less effective when prescribed by a family doctor than when prescribed by psychiatrists, who are specialists in mental disorders and more familiar with the nuances of such treatment (Lin et al., 2000; Wang et al., 2005; Wilson, Duszynski, & Mant, 2003). Responding to general practitioners, medical staff in hospitals' emergency departments must also determine whether some individuals who arrive there have a psychological disorder and, if so, what immediate treatment to recommend.

Mental Health Professionals with Master's Degrees

In addition to psychiatric nurses, some other mental health professionals have master's degrees. Most **social workers** have an M.S.W. (master of social work) degree and may have had training to provide psychotherapy to help individuals and families. Social workers also teach clients how to find and benefit from the appropriate social services offered in their community. For example, they may help clients to apply for Medicare or may facilitate home visits from health care professionals. Most states also license *marriage and family therapists* (M.F.T.s), who have at least a master's degree and are trained to provide psychotherapy to couples and families. Other therapists may have a master's degree (M.A.) in some area of counseling or clinical psychology, which indicates that their training consisted of fewer courses and research experience, and less supervised clinical training than that of their doctoral-level counterparts. Some counselors may have had particular training in *pastoral counseling*, which provides counseling from a spiritual or faith-based perspective.

Table 3.5 reviews the different types of mental health clinicians.

Table 3.5 ▶ Clinicians Who Diagnose Mental Disorders

Type of Clinician	Specific Title and Credentials
Doctoral-Level Psychologists	Clinical psychologists (including clinical neuropsychologists) and counseling psychologists have a Ph.D., Psy.D., or Ed.D. degree and have advanced training in the treatment of mental illness.
Medical Personnel	Psychiatrists and general practitioners have a M.D. degree; psychiatrists have had advanced training in the treatment of mental illness. Psychiatric nurses have a M.S.N. degree and have advanced training in the treatment of mental illness.
Master's-Level Mental Health Professionals	Social workers with a master's degree (M.S.W.), marriage and family therapists (M.F.T.), and master's level counselors (M.A.) are mental health clinicians who have received specific training in helping people with problems in daily living or with mental illness. Psychiatric nurses have master's level training.

Psychiatric nurse

A mental health professional who has an M.S.N. degree, plus a C.S. certificate in psychiatric nursing.

Social worker

A mental health professional who has an M.S.W. degree and may have had training to provide psychotherapy to help individuals and families.

Key Concepts and Facts About Diagnosing Psychological Disorders

- Among other purposes, classification systems for diagnosis allow: (1) patients to be able to put a name to their experiences and to learn that they are not alone; (2) clinicians to distinguish “normal” from “abnormal” psychological functioning and to group together similar types of problems; and (3) researchers to discover the etiology, course, and effectiveness of treatments for abnormal psychological functioning.
- Classification systems also have drawbacks. They can be subject to diagnostic bias—perhaps on the basis of the patient’s sex, race, or ethnicity. For some people, being diagnosed with a psychological disorder is experienced as stigmatizing, which changes how the person feels about himself or herself or is seen by others.
- Classification systems should be both reliable and valid. Reliability is less likely when the criteria for disorders are not clear and when the criteria for different disorders significantly overlap.
- The most commonly used classification system in the United States is the *Diagnostic and Statistical Manual of Mental Disorders*, presently in its fourth edition, text revision (DSM-IV-TR). The DSM-IV-TR:
 - generally does not focus on etiology (the causes of disorders), but instead focuses on what can be observed rather than inferred;
 - lists explicit criteria for each disorder and includes a multiaxial system for clinicians and researchers to record diagnoses as well as additional information (medical status, comorbid psychological disorders, psychosocial and environmental problems, assessments of current and past functioning) that may affect diagnosis, prognosis, and treatment.
- DSM-IV-TR has been criticized on numerous grounds:
 - What constitutes clinically significant distress or impaired functioning is subjective and can vary widely from one clinician to another.
 - Disorders are classified as categorical rather than as on continua.
 - The way the criteria are structured leads to heterogeneous groups being diagnosed with the same disorder.
 - Every criterion for a given disorder is generally weighted equally to the others.
 - The duration criteria can be arbitrary and not necessarily supported by research.
 - Some sets of criteria are too restrictive.
 - With each edition of the DSM, the number of psychological disorders grows (DSM-IV-TR identifies almost 300 disorders). Many diagnoses have been created in order to ensure payment from health insurance providers.
 - Diagnoses have been added for disorders that clearly are medical problems.
 - Social factors that lead or contribute to psychological disorders are deemphasized.
 - There is a high comorbidity rate: Half the people diagnosed with one disorder have at least one other disorder.
 - Commonalities that underlie disorders across the categories are difficult to identify.
- Psychological disorders are generally diagnosed by clinical and counseling psychologists, psychiatrists, psychiatric nurses, and social workers. Other clinicians in a position to diagnose psychological disorders include general practitioners, pastoral counselors, and marriage and family therapists. Each type of clinician has received somewhat different training and therefore may gather different types of information and use that information in different ways.

Assessing Psychological Disorders

People came to know about Rose Mary and Rex Walls through the eyes of their daughter, Jeannette. In her memoir, Jeannette reports incidents that seem to be clear cases of neglect and irresponsible behavior. How might a mental health clinician or researcher have gone about assessing Rose Mary’s or Rex’s mental health? Although mental health clinicians might read Jeannette Walls’s memoir, hear her speak about her parents, or even see brief video clips of Rose Mary Walls, the information conveyed by those accounts isn’t adequate to make a clinical assessment: Jeannette’s memoir—and Rose Mary’s brief statements on videotape—portray what Jeannette and the video directors chose to include; we don’t know about events that were not discussed or portrayed, and we don’t know how accurate Jeannette’s childhood memories are. Other people’s accounts of an individual’s mental health generally provide only narrow slices of information—brief glimpses *as seen from their own points of view*, none of which is that of a mental health clinician. Without use of the formal tools and techniques of clinical assessment, any conclusions are likely to be speculative.

Were it possible to obtain information about Rose Mary and Rex Walls directly, what specific information would a clinician want to know in order to make a diagnosis and recommendations for treatment? More generally, what types of information are included in a clinical assessment? The answer depends, in part, on several factors related to the assessment:

- *The reason for the assessment* determines the questions that are to be asked and answered by the assessment; possible reasons for making an assessment include:
 - *To obtain additional information in order to make a diagnosis;*
 - *To monitor the course of the symptoms;*
 - *To determine what type of treatment might be most beneficial;* or
 - *To monitor the progress of treatment.*
- *The type of clinician making the assessment* determines, by virtue of his or her training, the types of information to be obtained.
- *The setting in which the clinician works* determines how much information is gathered; if the assessment is part of a research project, it may be more comprehensive than an assessment that is not part of a research project.
- *Financial issues related to the assessment* determine what specific methods of obtaining information will—and will not—be paid for. Health insurance companies, for instance, may be reluctant to pay for assessment methods that are not crucial in determining diagnosis or appropriate treatment.

Just like classification systems, assessment tools and techniques must be *reliable*. Other clinicians or researchers who make a clinical assessment of the same patient using the same method should obtain the same information. Similarly, assessment tools and techniques should be *valid*—they should assess the problem or aspect of functioning that they are intended to assess. And just because an assessment tool or technique is reliable, that doesn't necessarily mean it is valid. For instance, a questionnaire designed to assess the extent of an individual's preoccupying worries might be very reliable, but the questions might ask about preoccupying thoughts generally. If so, then people newly in love (and preoccupied with thoughts of their new partner) would achieve high scores; in that case, the test might measure *preoccupation* reliably, but not be a valid measure of preoccupation with worries per se.

In addition, clinicians should take into account an individual's cultural background when determining which assessment tools to use and how to interpret the resulting information. Not all assessment tools have comparison data for people from various ethnic backgrounds; comparing an individual's data or scores against those of a culturally dissimilar group will provide information that is not necessarily valid (Poortinga, 1995).

A complete clinical assessment can include various types of information about three main categories of factors: neurological and other biological factors (the structure and functioning of brain and body), psychological factors (behavior, emotion and mood, mental processes and contents, past and current ability to function), and social factors (the social context of the patient's problems, the living environment and community, family history and family functioning, history of the person's relationships, and level of financial resources and social support available). Most types of assessment focus primarily on one type of factor. We'll consider assessments of each of these main types of factors in the following sections.

Assessing Neurological and Other Biological Factors

In some cases, clinicians assess neurological (and other biological) functioning in order to determine whether abnormal mental processes and mental contents, affect, or behaviors arise from a medical problem, such as a brain tumor or abnormal hormone levels. In other cases, researchers seek to understand neurological and other biological factors that may be related to a particular disorder, because this

information might provide clues for possible treatments. Although neurological (and other biological) factors are not generally part of the DSM criteria for diagnosing mental disorders, the search for neurological and other biological markers or indicators of various psychological disorders has proceeded at a rapid pace over the past decade. It is clearly only a matter of time before these sorts of factors will be part of the standard diagnostic criteria for many psychological disorders.

Assessing Abnormal Brain Structures with X-Rays, CT Scans, and MRIs

Some psychological disorders, such as schizophrenia, appear to involve structural abnormalities of the brain. This is why clinical assessments sometimes make use of scans of a patient's brain. *Neuroimaging techniques* provide images of the brain. The oldest neuroimaging technique involves taking pictures of a person's brain using *X-rays*. A computer can then analyze these X-ray images and reconstruct a three-dimensional image of the brain. **Computerized axial tomography (CT)** (*tomography* is from a Greek word for "section") builds an image of a person's brain, slice by slice, creating a CT scan (sometimes called a CAT scan).

A more recent technology, **magnetic resonance imaging (MRI)**, makes especially sharp images of the brain, which allows more precise diagnoses when brain abnormalities are subtle. MRI makes use of the magnetic properties of different atoms, which resonate at different frequencies. Here's the basic idea: First, a large magnet is turned on, which causes atoms in the brain to line up with its magnetic field. Each atom has a north and south pole. Because opposite magnetic poles attract and like poles repel, the atoms become aligned with the magnetic field. Second, another magnetic field, presented from a different angle, is activated. This field will turn some of the atoms away from their alignment with the first field. Which atoms are affected by this second field? This depends on the rate at which this second field is pulsing: Different kinds of atoms resonate with different frequencies of pulses and align with this second magnetic field. The crucial part of an MRI is that when the second field is turned off completely, the atoms that had lined up with it will now reorient themselves with the first field. When the atoms that oriented with the second field move back to be aligned with the first one, they create a signal that can be recorded. This signal is translated into an image that shows where the atoms were located. By detecting different atoms and combining the signals into images, MRI can indicate the location of damaged tissue and can reveal particular parts of the brain that are larger or smaller than normal. For instance, an MRI can reveal the shrinkage of brain tissue that typically arises with chronic alcoholism (Rosenbloom, Sullivan, & Pfefferbaum, 2003); had Rex Walls had an MRI, it might well have shown that his brain had such shrinkage.

CT scans and MRIs can provide amazing images of the structure of the living brain. For example, some people with schizophrenia have larger ventricles (interior, fluid-filled spaces in the brain) than do people who do not have the disorder (Schneider-Axmann et al., 2006). These larger ventricles may occur, at least in part, because some of the surrounding brain tissue is smaller than normal, particularly in the thalamus (Gaser et al., 2004).

Assessing Brain Function With PET Scans and fMRI

Some mental disorders are associated not with abnormal brain structures (physical makeup), but rather with abnormal brain functioning (how the brain operates). By analogy, a laptop computer can fail to read CDs because the drawer for the CD won't open or the disk won't fit in the slot (a structural problem) or because the program that reads the disks gets corrupted (a functional problem). In a similar way, the brain can produce abnormal thoughts, feelings, and behaviors because either its structure or its functioning is awry. Researchers use different types of brain scans to assess brain functioning.

Schizophrenia

No schizophrenia

People with schizophrenia tend to have abnormally large ventricles (fluid-filled spaces in the brain). Compare these two images: The ventricles are indicated by the red arrows.

Daniel Weinberger, M.D., NIMH Clinical Brain Disorders Branch

We've just talked about how certain neuroimaging techniques can reveal brain structure, but how can researchers observe brain functioning? A key fact is that when a part of the brain is active, more blood (which transports oxygen and nutrients) flows to it, a little like the way that more electricity flows into a house when more appliances are turned on. The neurons draw more blood while they are sending and receiving signals than they do when they are not activated, because the activity increases their need for oxygen and nutrients. Because neurons in the same area of the brain tend to work together, specific areas of the brain will have greater blood flow while a person performs particular tasks.

In the field of psychopathology, researchers use functional neuroimaging to identify brain areas related to specific aspects of a disorder. For example, in one study, researchers asked participants with social phobia, who were afraid of speaking in public, to speak to a group and also to speak in private while their brains were scanned. As shown in Figure 3.2, speaking in public activated key parts of the limbic system, particularly the amygdala, more than did speaking in private (Tillfors et al., 2001). As noted in Chapter 2, the amygdala is involved in strong emotion, particularly fear. This part of the brain was not activated when people without a social phobia were tested. Other researchers have reported similar results for other sorts of phobias (Pissioti et al., 2003; Rauch et al., 1995).

The functional neuroimaging technique used in the study of social phobia just described was **positron emission tomography (PET)**, one of the most important methods for measuring blood flow (or energy consumption) in the brain. PET requires introducing a very small amount of a radioactive substance into the bloodstream. While a person performs a task, active regions of the brain take up more blood (and thus more of the radioactive substance) than less active regions. The relative amounts of radiation from different areas of the brain are measured and sent to a computer, which constructs a three-dimensional image of the brain that shows the levels of activity in the different areas. In PET images, higher radiation (greater activity) typically is indicated with brighter colors. PET scanning has drawbacks, such as the need to introduce radioactive substances and the need to have the person perform the same task for at least 40 seconds; in addition, a single test can cost \$2,000.

Figure 3.2

3.2 ► Social Phobia and the Amygdala Results from PET scans showing increased activation in the region of the amygdala when people with social phobia spoke to an audience compared to when they spoke in private; brighter colors indicate greater activation. The PET results are superimposed on an MRI scan to show the location of activated areas (Tillfors et al., 2001).

Computerized axial tomography (CT)

A neuroimaging technique that uses X-rays to build a three-dimensional image (CT or CAT scan) of the brain.

Magnetic resonance imaging (MRI)

A neuroimaging technique that creates especially sharp images of the brain by measuring the magnetic properties of atoms in the brain; MRI allows more precise diagnoses when brain abnormalities are subtle.

Positron emission tomography (PET)

A neuroimaging technique that measures blood flow (or energy consumption) in the brain and requires introducing a very small amount of a radioactive substance into the bloodstream.

Functional magnetic resonance imaging (fMRI) is currently the most widely used method for measuring human brain function. Neuroimaging with fMRI typically relies on three facts: (1) Iron affects the way that the hydrogen atoms in water molecules respond to the magnetic fields used in fMRI. (2) The presence of oxygen diminishes this effect of iron. (3) Hemoglobin, the crucial component of red blood cells that allows them to carry oxygen throughout the body and brain, has iron atoms in its structure. The key here is that the effects of the iron are different when the hemoglobin carries oxygen than when it has been stripped of its oxygen (because the oxygen was used for cell metabolism). When a region of the brain is activated, it draws blood more quickly than the oxygen carried by the hemoglobin in the blood can be used. This means that red blood cells with oxygenated hemoglobin accumulate in the activated region—and this increase is what is measured in an fMRI scan. Brain regions that are not activated (or are activated less strongly) when a person is performing a particular task (such as speaking in public or looking at pictures) draw less blood, and the oxygen carried by the blood gets used up. The difference in oxygen levels due to brain activity is reflected in the fMRI images.

The advantages of fMRI over PET include the absence of radiation and the ability to construct brain images showing activation that occurs in just a few seconds. Disadvantages include the requirement that a participant must lie very still in the narrow tube of a noisy machine (which some people find uncomfortable); in addition, any metal object containing iron cannot be brought into the machine.

Neither PET nor fMRI simply detects which parts of the brain are “on” or “off” at a particular time. Even at rest, the brain is never completely “off,” so activity in the brain during a particular task is always measured *relative* to activity during another condition. In many neuroimaging studies, researchers compare activity when the participants are performing a given task with activity when they are “resting.” However, researchers cannot know what is happening in the brain while a particular participant is at rest. For instance, even if two participants are both daydreaming while supposedly at rest, they may be thinking about different things, which would produce different resting states in their brains. A person with depression might be thinking about how hopeless everything seems, whereas someone with schizophrenia may be thinking about a particular delusion. The same stimulus in the task itself might affect the two participants’ brains differently, but the two resting states are already different. When the brain activity during performance of the task is compared to that in the resting state, how much of the observed difference is due to the stimulus in the task and how much is due to differences in the resting state? Designing proper comparison tasks is a major challenge in functional neuroimaging studies.

Neurotransmitter and Hormone Levels

Many researchers study how biochemical imbalances contribute to mental illness. However, researchers are just beginning to develop reliable ways to assess neurotransmitter levels in functioning human brains (Gujar et al., 2005). **Magnetic resonance spectroscopy (MRS)** relies on magnetic resonance to assess levels of neurotransmitter substances in the brain. For example, Smith and her colleagues (2001) used MRS to scan the brains of children whose mothers used cocaine while they were pregnant, thereby exposing their unborn infants to this drug. Even though the children were, on average, 8 years old at the time of scanning, they had abnormally high amounts of creatine (a chemical involved in supplying energy to neurons and muscles) in their frontal lobes. High levels of this substance indicate increased numbers of glial cells, which may be attempting to repair damaged tissue. If, in fact, the children’s frontal lobes were damaged, the damage could contribute to a range of psychological disorders—including problems inhibiting aggression.

Functional magnetic resonance imaging (fMRI)

A neuroimaging technique that uses MRI to obtain images of brain functioning, which reveal the extent to which different brain areas are activated during particular tasks.

Magnetic resonance spectroscopy (MRS)

A neuroimaging technique that uses magnetic resonance to assess levels of neurotransmitter substances in the brain.

In addition to using MRS, researchers measure the levels of chemical by-products of neurotransmitters in blood, urine, or cerebrospinal fluid (the fluid that surrounds the brain and spinal cord) in order to get a sense of the role of neurotransmitters in psychological disorders. For example, Geraciotti and colleagues (2006) studied the cerebrospinal fluid of patients who had major depression or posttraumatic stress disorder (PTSD) and found in both groups higher than normal levels of a by-product of *substance P* (a neurotransmitter substance known to be involved in registering pain). The researchers also found that more of this by-product was present when the patients with PTSD viewed aversive videos (which triggered their symptoms) than when they viewed neutral videos. Such studies can not only provide information about neurological and other biological differences that characterize people who have different disorders, but also help reveal why specific stimuli can exacerbate the symptoms of a disorder.

Furthermore, PET techniques that use *ligands*, radioactive molecules that mimic neurotransmitters, can reveal where receptors for given neurotransmitters are located in the brain. As noted in Chapter 2, some aspects of mental illness may be related to dysfunctional receptor systems. For example, Tauscher and colleagues (2001) injected a ligand that mimics serotonin into the blood of healthy volunteers and observed how much of that ligand bound to one type of serotonin receptor. They also found that people who had higher levels of anxiety showed less binding of this ligand.

Researchers and clinicians also want to assess the levels of specific hormones to determine whether they may contribute to mental illness. For instance, symptoms of depression are sometimes caused by low levels of the hormone *thyroxin*, which is measured by a blood test (Pfennig et al., 2004). Depressed individuals who have low levels of thyroxin might be prescribed thyroid supplements as part of their treatment (Altshuler et al., 2001).

Neuropsychological Assessment

An assessment of neurological factors may include **neuropsychological testing**, which uses behavioral responses to test items in order to draw inferences about brain functioning. Assessing neuropsychological functioning allows clinicians and researchers to distinguish the effects of brain damage from the effects of psychological problems (for example, disrupted speech can be caused by either of these). Neuropsychological assessment is also used to determine whether brain damage is contributing to psychological problems (for example, frontal lobe damage can disrupt the ability to inhibit aggressive behavior). Unlike functional neuroimaging, which identifies brain areas activated during a given task (relative to another task), neuropsychological testing gives a broad picture of the brain's functioning. A neuropsychological assessment determines the sorts of basic functions that the brain can do effectively, can do with effort, or cannot perform. Moreover, the results can suggest that specific parts of the brain may be damaged. Although much less precise, such testing is significantly less expensive and easier to administer than neuroimaging, and it can be given in any quiet room.

Neuropsychological tests range from those that assess complex abilities (such as judgment or planning) to those that assess a relatively specific ability, such as the ability to recognize faces (measured by the Facial Recognition Test; Benton et al., 1983). For example, in one version of the Facial Recognition Test, a patient is shown a photo of a "target" face, then a set of six photos of faces from which the patient must pick out the target. In another version of the Facial Recognition Test, the six photos differ in lighting or orientation, and the patient must pick out the three that show the target face. Other neuropsychological tests, such as the Bender Visual-Motor Gestalt Test-II (2nd edition) (Bender, 1963; Brannigan & Decker, 2003), assess more

Neuropsychological testing

The employment of assessment techniques that use behavioral responses to test items in order to draw inferences about brain functioning.

The Rey Osterrieth Test requires the test-taker to copy a complex figure, and then draw it from memory; the test assesses visual perception, organizational ability, and memory.

Photo Edit

complex functions. In the Bender Visual-Motor Gestalt Test, patients are shown a series of drawings that range from simple to complex and are asked to reproduce them. This test assesses the integration of visual and motor functioning, which involves many distinct parts of the brain. The test may be used to help diagnose various problems, including learning disorders and memory problems (Brannigan & Decker, 2006).

There are also sets of neuropsychological tests, such as the Luria-Nebraska Neuropsychological Battery (Golden, Hammekke, & Purisch, 1980), which consists of 14 tests that measure different abilities, or the Halstead-Reitan Neuropsychological Battery (Reitan & Davison, 1974), which consists of 10 tests that measure different abilities. When specific neuropsychological tests suggest possible brain areas that may be affected, the status of those areas can be verified by neuroimaging. A neuropsychologist may administer a whole battery of tests or only specific tests, depending on the reason for the assessment and what information is already known about the patient's brain damage and ability to function.

Assessing Psychological Factors

If Rose Mary and Rex Walls had been willing to see a mental health clinician, how would the clinician have gone about assessing psychological factors relating to their unusual behavior and beliefs? What would such an assessment entail? During an assessment, clinicians and researchers often seek to identify the ways in which psychological functioning is disordered and the ways in which it is not. For instance, a clinical assessment would shed light on the extent to which Rex Walls's problems were primarily a result of his drinking or arose from underlying impairments that may have been masked by his pronounced drinking. According to Jeannette's memoir, during the two stretches when Rex was sober, his functioning significantly improved.

Certain areas of psychological functioning—mental processes and mental contents, affect, and behavior—are often directly related to DSM-IV-TR criteria for specific disorders. Further, these areas are frequently the most relevant for determining a person's current and future ability to function in daily activities.

Mental health researchers and clinicians employ a variety of assessment techniques and tools to ascertain psychological functioning, including interviews and tests of cognitive and personality functioning. Which tools and techniques are used depends on the purpose of the assessment. In the case of Rex and Rose Mary Walls, the purpose of the assessment could be to determine whether either one or both of them: (1) was so impaired that he or she posed a potential imminent danger to self or others, and thus might best be admitted to a psychiatric unit of a hospital to be observed around the clock; (2) was impaired enough to qualify for disability payments; (3) had a psychological disorder, and if so, what specific disorder it was and what type of treatment might be appropriate. If an assessment had been made while Rex and Rose Mary's children were still living with them, it could have helped the clinician determine whether either or both parents were competent to be responsible for their underage children.

Clinical Interview

An important tool used to assess psychological functioning is the **clinical interview**, a meeting between clinician and patient during which the clinician asks questions related to the patient's symptoms and functioning. A clinical interview provides two types of information: the content of the answers to the interview questions, and the manner in which the person answered them (Westen & Weinberger, 2004). Questions may focus on symptoms, general functioning, degree and type of impairment, and the patient's relevant history.

In an *unstructured interview*, the clinician asks whatever questions he or she deems appropriate, depending on the patient's responses. In contrast, in a *structured interview*, the clinician uses a fixed set of questions to guide the interview. The advantage of an unstructured interview is that it allows the clinician to pursue

Clinical interview

A meeting between clinician and patient during which the clinician asks questions related to the patient's symptoms and functioning.

topics and issues specific to the patient. However, different clinicians who use this approach to interview the same patient may arrive at different diagnoses, because each clinician's interview may cover different topics and therefore gather different information. Another problem with unstructured interviews is that the interviewer may neglect to gather important information about the context of the problem and the individual's cultural background. In contrast, a structured interview is likely to yield a more reliable diagnosis because each clinician asks the same set of questions. However, such a diagnosis may be less valid, because the questions asked may not be relevant to the patient's particular symptoms, issues, or concerns (Meyer, 2002). That is, different clinicians using a structured interview may agree on the diagnosis, but all of them may be missing the boat about the nature of the problem and may diagnose the wrong disorder. A *semistructured interview* combines elements of both of the other types: Specific questions guide the interview, but the clinician also has the freedom to pose additional questions that may be relevant, depending on the patient's answers to the standard questions.

Observation

All types of interviews provide an opportunity for the clinician or researcher to observe and make inferences about different aspects of a patient:

- *Appearance.* Has he or she bathed recently? Is he or she dressed appropriately? In addition to these obvious aspects of appearance, signs of disorders can sometimes be noted by carefully observing subtle aspects of a person's appearance. For example, patients with the eating disorder bulimia nervosa (to be discussed in Chapter 10) may regularly induce vomiting; as a result of repeated vomiting, their parotid glands, located in the cheeks, may swell and create a somewhat puffy look to the cheeks (similar to a chipmunk's cheeks). Such patients may also have scars on their hands where repeated exposure to stomach acid has damaged the skin (which occurs when they put their hands down their throats to induce vomiting).
- *Behavior.* The patient's body language, facial expression, movements, and speech can provide insights into different aspects of psychological functioning:
 - *Emotions.* What emotions does the patient convey? The clinician can observe the patient's expression of distress (or lack thereof) and emotional state (upbeat, "low," intense, uncontrollable, inappropriate to the situation, or at odds with the content of what the patient says).
 - *Movement.* The patient's general level of movement—physical restlessness or a complete lack of movement—may indicate abnormal functioning.
 - *Speech.* Clinicians observe the rate and contents of the patient's speech: Speaking very quickly may suggest anxiety, mania, or certain kinds of substance abuse; speaking very slowly may suggest depression or other kinds of substance abuse.
 - *Mental processes.* Do the patient's mental processes appear to be unusual or abnormal? Does the patient appear to be talking to someone who is not in the room, which would suggest that he or she is having hallucinations? Can the patient remember what the clinician just asked? Does the patient flit from topic to topic, unable to stay focused on answering a single question?

Another aspect of the patient's speech that clinicians may note is whether it follows grammatical rules and a logical pattern. Here's a clear example of an abnormal speech pattern that indicates impaired mental processes: "If we need soap when you can jump into a pool of water, and then when you go to buy your gasoline, my folks always thought they should get pop, but the best thing is to get motor oil . . ." (Andreasen, 1979, p. 41).

Behaviors observed during a clinical interview can, in some cases, provide more information than the patient's report about the nature of the problem. In other cases, such observations round out an assessment; it is the patient's own report of the problem—its history and related matters—that provides the foundation of the

interview. In any case, the clinician must keep in mind that “unusual” behavior should perhaps be interpreted differently for patients from different cultural backgrounds. For instance, Japanese people, as a rule, express less emotion in their faces (Ekman, 1984). A clinician should not necessarily interpret a Japanese immigrant’s reduced emotional expression as indicating flat affect. Conversely, should a Japanese immigrant display anger that would seem “normal” for an American, the clinician might inquire further about the patient’s anger and ability to control his or her emotions. Moreover, the same principle applies to different age groups; for example, what is usual for a middle-aged adult might not be usual for an older adult (Baden & Wong, 2008).

Patient’s Self-Report

Some symptoms cannot be observed directly, such as the hallucinations that characterize schizophrenia, or the worries and fears that characterize some anxiety disorders. Thus, the patient’s own report of his or her experiences becomes a crucial part of the clinical assessment.

At some point in the interview process, the clinician will ask about the patient’s history—past factors or events that may illuminate the current difficulties. For example, the clinician will ask about current and past psychiatric or medical problems and about how the patient understands these problems and possible solutions to them. The clinician will inquire about substance use, sexual or physical abuse or other traumatic experiences, economic hardships, and relationships with family members and others. This information helps the clinician put the patient’s current difficulties in context and determine whether his or her psychological functioning is maladaptive or adaptive, given the environmental circumstances (Kirk & Hsieh, 2004).

Some patients, however, intentionally report having symptoms that they don’t actually have or exaggerate symptoms they do have, either for material gain or to avoid unwanted events (such as criminal prosecution)—such behavior is the hallmark of **malinger**ing. For instance, a malingering soldier may exaggerate his or her anxiety symptoms and claim to have posttraumatic stress disorder in order to avoid further combat. Malingering contrasts with **factitious disorder**, which occurs when someone intentionally pretends to have symptoms or even induces symptoms so that he or she can assume a “sick” role and receive attention. A soldier with factitious disorder might exaggerate or invent anxiety symptoms *not* to avoid combat, but for the attention he or she might receive from other soldiers or from clinicians. Whereas both malingering and factitious disorder involve deception—inventing or exaggerating symptoms—the motivations are different. Unlike those with malingering, people with factitious disorder do not deceive others about their symptoms for material gain or to avoid negative events.

Most patients intend to report their current problems and history as accurately as possible. Nevertheless, even honest self-reports are subject to various biases. Most fundamentally, patients may accurately report what they remember, but their memory of the frequency, intensity, or duration of their symptoms may not be entirely accurate. As we noted in Chapter 2, emotion can bias what we notice, perceive, and remember.

Another bias that can affect what patients say about their symptoms is *reporting bias*—inaccuracies or distortions in a patient’s report because of a desire to appear in a particular way (Meyer, 2002). In some cases, patients may not really know the answer to a question asked in a clinical interview. For instance, when asked, “Why did you do that?” they may not have thought about their motivation before and may not *really* be aware of what it was, but instead create an answer on the spot (Westen & Weinberger, 2004).

In other cases, people’s psychological functioning is sufficiently impaired that they confuse their internal world—their memories, fears, beliefs, fantasies, or dreams—with reality, which leads to inaccuracies in self-reports; delusions are such an impairment. For instance, Rex Walls frequently told stories about his past, including his

Malingering

Intentional false reporting of symptoms or exaggeration of existing symptoms, either for material gain or to avoid unwanted events.

Factitious disorder

A psychological disorder marked by the false reporting or inducing of medical or psychological symptoms in order to assume a “sick” role and receive attention.

years with the Air Force; his stories often involved his heroic actions that saved others (such as fixing a broken sluiceway at Hoover Dam or safely landing a plane after an engine failed). According to Jeannette, “Dad always fought harder, flew faster, and gambled smarter than everyone else in his stories. Along the way, he rescued women and children and even men who weren’t as strong and clever” (Walls, 2005, p. 24). A clinical assessment could help determine the extent to which Rex’s stories were merely embellishments to make him look good or were delusions. It can be useful to obtain information from family, friends, or other people who are in a position to confirm or modify a patient’s report in order to distinguish delusions from embellishments.

Here’s an example of how simply asking patients about themselves during clinical interviews may not always lead to an accurate picture of their psychological functioning, despite their honesty. One of the authors of this book (Rosenberg) once worked in a hospital emergency room, evaluating people who came to the emergency room for psychiatric reasons. One day, she was asked to interview a man in his 30s who was dressed appropriately and spoke somewhat slowly. He had a history of schizophrenia and depression, and his psychiatrist was affiliated with the hospital. The patient reported that he came to the hospital because his mother wanted him to come (in fact, she drove him there), but he wasn’t exactly sure why. He said that he wasn’t hearing voices, and he didn’t feel sad, depressed, or suicidal. In response to questions, his mental processes and mental contents seemed normal. Rosenberg telephoned his psychiatrist, who was puzzled about why the patient had come to the emergency room. The psychiatrist could shed no light on the matter; he had an appointment scheduled with the patient the following week, but he did not know why the patient’s mother brought him to the hospital.

Rosenberg asked the patient’s permission to speak with his mother; he consented. The mother, a woman in her 60s, reported that she thought her son had been more depressed lately. She went on to explain that for the last month he hadn’t gotten out of bed unless he had a doctor’s appointment. On those days, she harangued him until he bathed, groomed himself, and put on appropriate clothes (as she had also done the day he came to the emergency room). The other days he stayed in bed in his pajamas. When Rosenberg spoke to the psychiatrist, he had not known that his patient was depressed, or that the only reason the patient was appropriately dressed and groomed for appointments was because of his mother’s insistence. When Rosenberg then spoke with the patient again, explaining what the mother had said, he admitted that he had a hard time getting out of bed, and didn’t have much energy or interest in things, although he didn’t *feel* depressed. He agreed that it made sense for him (and his mother) to be interviewed by staff in the inpatient psychiatric unit to determine whether he should be hospitalized; Rosenberg did not see him again, but later found out that he in fact had been hospitalized for depression.

This experience brings home the limitations of relying solely on people’s self-reports of their emotional states (Achenbach et al., 2005; Meyer, 2002). This patient said that he didn’t feel depressed, but key aspects of his behavior at home, in particular, his difficulty getting out of bed and his lack of energy or interest in previously interesting activities, were clear symptoms of depression. But because the patient didn’t realize that these behaviors were a problem, he didn’t report that he was having those symptoms. Thus, although a patient’s self-report is important, it has limitations. Similarly, when interviewing children, the clinician must be sensitive to the fact that they may lack adequate insight and/or the verbal ability to be reliable reporters of their mental health status.

Semistructured Interviews

Because clinicians sometimes want to be sure to cover specific ground with their questions, they may use a semistructured interview format, asking a list of standard questions but formulating their own follow-up questions. The follow-up questions are based on patients’ responses to the standard questions. One set of questions that assesses a patient’s mental state at the time of the interview is the *mental status exam*. In a mental status exam, the clinician asks the patient to

Creatas/Punchstock

Some problematic behaviors may be obvious to a mental health professional while interacting with a patient. Other behaviors, which occur infrequently or only in specific types of environments, such as avoiding stepping on cracks (which some people with obsessive compulsive disorder do) are less likely to be observed. If the patient doesn’t view these behaviors as a problem, he or she may not report them.

As part of the mental status exam, patients are asked whether they know their own name, the date and year, and who is currently president. Patients who do not know these facts may have some type of memory impairment. Further tests will be done to determine the specific memory problems, their cause, and possible treatments.

describe the problem, its history, and the patient's functioning in different areas of life. Other standard questions in the mental status exam probe the patient's ability to reason, to perform simple mathematical computations, and to assess possible problems in memory and judgment. The clinician uses the patient's answers to the standard questions to develop hypotheses about possible diagnoses and difficulties with functioning, and then asks other questions to obtain additional information. For instance, as part of the mental status exam, patients are routinely asked whether they remember their own name, the date and year, and who is president. If the patient doesn't remember correctly who the current president is, the clinician might ask other, more detailed questions involving different aspects of memory—such as memories of other languages spoken, of more distant events or important personal events in the recent past—which may reflect an underlying neurological problem. People from other cultures may answer some of the questions in a mental status exam in unconventional ways, and clinicians must take care not to infer that “different” is “abnormal.”

The mental status exam assesses cognitive, emotional, and behavioral functioning broadly, and the standard questions are not designed to obtain specific information that corresponds to the categories in DSM-IV-TR. The interviewer can arrive at a diagnosis based on answers to both standard and follow-up questions, but the goal of the mental status exam is more than diagnosis: It seeks to create a portrait of the individual's general psychological functioning.

The mental status exam contrasts with another semistructured interview format—the *Structured Clinical Interview for DSM-IV, Axes I and II* (SCID-I and SCID-II; First et al., 1997, 2002), which is generally used when the interview is part of a research project and is designed to assist the researcher in diagnosing patients according to the DSM-IV-TR. The SCID provides modules that correspond to different categories of disorders. Each module starts off with a question to assess whether the individual has symptoms related to that category of disorders. If the patient does not have such symptoms, the rest of the questions in the module are skipped. If symptoms are present, the SCID lists the questions the interviewer should ask. The questions correspond to DSM-IV-TR criteria lists, such as that in Table 3.4. Based on the patient's responses, the interviewer can readily determine which disorder (if any) is the most appropriate diagnosis. Such DSM-related tools generally do not require the interviewer to interpret patients' answers.

Clinical interviews provide a wealth of information, about the patient's symptoms and the patient's general functioning, as well as about the context in which the symptoms arose and continue. However, a thorough clinical interview can be time-consuming and may not be as reliable and valid as assessment techniques that utilize tests.

Tests of Psychological Functioning

Many different tests are available to assess different areas of psychological functioning. Some tests assess a relatively wide range of abilities and areas of functioning (such as intelligence or general personality characteristics). Other tests assess a narrow range of abilities, particular areas of functioning, or specific symptoms (such as the ability to remember new information or the tendency to avoid social gatherings).

Cognitive Assessment

One tool to assess cognitive functioning is an intelligence test. Clinicians typically use the *Wechsler Adult Intelligence Scale*, 4th edition (WAIS-IV, revised in 2008) or the *Wechsler Intelligence Scale for Children*, 4th edition (WISC-IV, revised in 2003), depending on the age of the patient. Numerical results of these tests yield an *intelligence quotient* (IQ); the average intelligence in a population is set at a score of 100, with normal intelligence ranging from 85 to 115. IQ scores of 70 to 85 are considered to be in the *borderline* range, and scores of 70 and below signify mental impairment. However, the single intelligence score is not the only important

information that the WAIS-IV and WISC-IV provide. Both of these tests include subtests that assess four types of abilities:

- *verbal comprehension* (i.e., the ability to understand verbal information);
- *perceptual reasoning* (i.e., the ability to reason with nonverbal information);
- *working memory* (i.e., the ability to maintain and mentally manipulate new information); and
- *processing speed* (i.e., the ability to focus attention and quickly utilize information).

In addition, the WAIS-IV and WISC-IV are devised so that the examiner can compare an individual's responses on each of the subtests to the responses of other people of the same age and sex. Information about specific subtests helps the examiner determine the individual's pattern of relative strengths and weaknesses in intellectual functioning.

Current versions of intelligence tests have been designed to minimize the influence of cultural factors, in part by excluding test items that might require cultural knowledge that is unique to one group (and would thus put members of other groups at a disadvantage) (Kaufman et al., 1995; Poortinga, 1995). Moreover, newer tests and revisions of older tests include specific norms for different ethnic groups.

Neuropsychological testing, described earlier, can also be used for cognitive assessment. Many of the tests in a typical neuropsychological battery assess basic cognitive functions, such as perception, memory, and language comprehension. Other cognitive testing focuses purely on cognitive functions, without any regard to which parts of the brain give rise to these functions. For example, memory tests can discover whether a person has significantly greater difficulty recalling events from the relatively distant past than recalling recent events.

Personality Assessment

Various psychological tests assess different aspects of personality functioning.

Inventories In order to assess general personality functioning, a clinician may use an *inventory*—a questionnaire with items pertaining to many different problems and aspects of personality. An inventory can indicate to a clinician what problems and disorders might be most likely for a given person. Inventories usually contain test questions that are sorted into different *scales*, with each scale assessing a different facet of personality. The most commonly used inventory is the *Minnesota Multiphasic Personality Inventory*, 2nd edition (MMPI-2; Butcher & Rouse, 1996). Originally developed in the 1930s to identify people with mental illness, it was revised in 1989 to include norms of people from a wider range of racial, ethnic, and other groups and to update specific items. The MMPI-2 consists of 567 questions about the respondent's behavior, emotions, mental processes, mental contents, and other matters. The respondent rates each question as being true or false about himself or herself. The inventory generally takes between 60 and 90 minutes to complete. (There is also a short form, with 370 items.) The inventory is available in three formats: paper and pencil, an audiocassette recording, and a computer version. The MMPI-2 has been translated into many languages and is used in many different countries.

Responses on the MMPI-2 are sorted into two types of scales: validity scales and clinical scales. *Validity scales* assess whether the individual's responses are likely to be valid—that is, whether they represent an accurate self-report. The validity scales assess the degree to which the respondent answers in order to appear psychologically healthier or more impaired than he or she actually is (as occurs with malingering or factitious disorder). If the score on any of the validity scales is extremely high, an individual's responses are thought to be invalid. *Clinical scales* assess symptoms of various disorders and problems (see Table 3.6). The pattern of scores on the various scales creates a profile, as illustrated in Figure 3.3. Different profiles are associated with different patterns of personality functioning and impairment.

Table 3.6 ▶ MMPI-2 Scales

Scale	Sample Item	What Is Assessed
? (Cannot Say)	The score is the number of items that were unanswered or answered as both true and false.	An inability or unwillingness to complete the test appropriately, which could indicate the presence of symptoms that interfere with concentration.
L (Lie)	Sometimes want to swear (F).	Attempts to present himself or herself in a positive way, not admitting even minor shortcomings.
F (Infrequency)	Something wrong with mind (T).	Low scores suggest attempts to try to fake appearing to have “good” mental health or psychopathology; high scores suggest some type of psychopathology.
K (Correction)	Often feel useless (F).	More subtle attempts to exaggerate “good” mental health or psychopathology. This scale is also associated with education level—more educated people score higher than those with less education.
1. Hs (Hypochondriasis)	Body tingles (F).	An abnormal concern over bodily functioning and imagined illness.
2. D (Depression)	Usually happy (F).	Symptoms of sadness, poor morale, and hopelessness.
3. Hy (Hysteria)	Often feel very weak (T).	A propensity to develop physical symptoms under stress, along with a lack of awareness and insight about one’s behavior.
4. Pd (Psychopathic Deviate)	Am misunderstood (T).	General social maladjustment, irresponsibility, or lack of conscience.
5. Mf (Masculinity-Femininity)	Like mechanics magazines (T for women).	The extent to which the individual has interests, preferences, and personal sensitivities more similar to those of the opposite sex.
6. Pa (Paranoia)	No enemies who wish me harm (F).	Sensitivity to others, suspiciousness, jealousy, and moral self-righteousness.
7. Pt (Psychasthenia)	Almost always anxious (T).	Obsessive and compulsive symptoms, poor concentration, and self-criticism.
8. Sc (Schizophrenia)	Hear strange things when alone (T).	Delusions, hallucinations, bizarre sensory experiences, and poor social relationships.
9. Ma (Hypomania)	When bored, stir things up (T).	Symptoms of hypomania—elated or irritable mood, “fast” thoughts, impulsiveness, and physical restlessness.
10. Si (Social Introversion)	Try to avoid crowds (T).	Discomfort in social situations and preference for being alone.

Note: (T) indicates that when the item is marked as true, it contributes toward a high score on the scale; (F) indicates that when the item is marked as false, it contributes toward a high score on the scale. The dark green rows above refer to the validity scales, and the light green rows refer to the clinical scales.

Projective test

A tool for personality assessment in which the patient is presented with ambiguous stimuli (such as inkblots or stick figures) and is asked to make sense of and explain them.

Although the MMPI-2 does help a clinician or researcher to understand the nature of various clinical disorders, the results do not yield a specific DSM-IV-TR diagnosis (because this test was not designed to do so).

Projective Tests Psychologists may also wish to assess facets of patients’ personalities that are less likely to emerge in a self-report, such as systematic biases in mental processes. In a **projective test**, the patient is presented with an ambiguous stimulus (such as an inkblot or a group of stick figures) and is asked to make sense of and explain the stimulus. For example, what does the inkblot look like, or what are the stick figures doing? The idea behind such a test is that the particular structure a patient imposes on the ambiguous stimulus reveals something about the patient’s mental processes or mental contents. This is the theory behind the well-known *Rorschach test*, which was developed by

Figure 3.3**B.3 ▶ An MMPI-2 Profile for Validity and Clinical Scales**

This is the MMPI-2 profile of a depressed 47-year-old man. His highest clinical scores are on the D and Pt scales, followed by Pd and Si. People with this profile typically are significantly depressed, agitated, and anxious. They may brood about their own deficiencies and have concentration problems (Greene, 2000).

Herman Rorschach (1884–1922). This test includes ten inkblots, one on each of ten cards. The ambiguity of the shapes permits a patient to imagine freely what the shapes resemble.

Rorschach tests and projective tests in general have been criticized for two related reasons (Anastasi, 1988; Entwisle, 1972): (1) They do not appear to be valid (that is, to assess what they are said to measure); and, (2) they are not necessarily reliable (the assessment of a patient on one day is not necessarily the same as an assessment made on another day). John Exner (1974) addressed these criticisms by developing a systematic, comprehensive scoring system for the Rorschach test. This system has been tested extensively with a variety of populations, and it has been shown to be reasonably reliable (Sultan et al., 2006). Research shows that Exner's system also assesses psychosis reasonably well (Dao & Prevatt, 2006; Garb et al., 2005; Meyer & Archer, 2001). However, it is not as effective in assessing psychological disorders in general (Lilienfeld et al., 2000; Wood, Lilienfeld, et al., 2001). Furthermore, the norms of Exner's scoring system might lead to misdiagnosing people as having a disorder they do not, in fact, have (Wood, Nezworski, et al., 2001). Thus, although the Rorschach test may provide information regarding aspects of a patient's personality and mental functioning, it is not the only tool available to do so, and it has clear drawbacks.

Another projective test, the *Thematic Apperception Test (TAT)*, uses detailed black-and-white drawings that often include people. The TAT was developed by Christiana Morgan and Henry Murray (1935) and is used to discern motivations, thoughts, and feelings without having to ask a person directly. The patient is asked to explain the drawings in various ways: The clinician may ask the patient what is happening in the picture, what has just happened, what will happen next, or what the people in the picture might be thinking and feeling. Like the Rorschach test, the TAT elicits responses that presumably reflect unconscious beliefs, desires, fears, or issues (Murray, 1943).

Responses on the TAT may be interpreted freely by the clinician or scored according to a scoring system. However, only 3% of clinicians who use the TAT rely on a scoring system (Pinkerman, Haynes, & Keiser, 1993). Furthermore, the TAT has been criticized because responses to the drawings can be ambiguous. In particular, a clinician cannot distinguish between a patient's thoughts, feelings, or usual behavior and how the person *wants* to think, feel, or behave (Lilienfeld, Wood, & Garb, 2000). This fundamental ambiguity calls into question the rationale for using the test, which is to understand the patient's mental processes and contents without having to ask about them directly.

Getty Images

The Rorschach test is a projective test that consists of inkblots. Patients are asked what each inkblot—like the one here—looks like. The Rorschach test is based on the idea that the test-taker imposes a structure onto the ambiguous inkblot; the patient's responses are thought to reveal something about himself or herself.

Lewis J. Merrim/Photo Researchers

As part of the Thematic Apperception Test, patients are asked to describe the motivations, thoughts, and feelings of people portrayed in various drawings. Some clinicians consider a patient's answers to reflect unconscious beliefs, feelings, and desires.

Assessing Social Factors

Symptoms arise in a context, and part of a thorough clinical assessment is collecting information about social factors. To some extent, the context helps the clinician or researcher understand the problems that initiated the assessment: How does the patient function in his or her home environment? Are there family factors or community factors that might influence treatment decisions? Is the patient from another culture, and if so, how might that affect the presentation of his or her symptoms or influence how the clinician should interpret other information obtained as part of the assessment?

The importance of social and environmental factors in making an assessment is illustrated by Arthur Kleinman (1988) in examples such as this: If a man has lost energy because he has contracted malaria, has a poor appetite as a result of anemia (due to a hookworm infestation), has insomnia as a result of chronic diarrhea, and he feels hopeless because of his poverty and powerlessness, does the person have depression? His symptoms meet the criteria for depression (as we shall see in Chapter 6), but isn't his distress a result of his health problems and social circumstances and their consequences? Summing up his experiences as depression might limit our understanding of his situation and the best course of treatment.

Family Functioning

As noted in Chapter 2, various aspects of family functioning can affect a person's mental health. This was certainly true of the Walls family, where Rex's drinking and irresponsibility led Rose Mary to become overwhelmed and to "shut down"—staying in bed for days and crying. Similarly, their marriage appeared to have a role in Rex's drinking problem: While living on the streets of New York, Rex developed tuberculosis and was hospitalized for 6 weeks, during which time he became sober. A hospital administrator helped him obtain a job as a maintenance man in a resort in upstate New York; Rose Mary didn't want to leave the city, so he went without her. He worked and lived at the resort for almost three seasons and continued to stay sober while he was there—his longest stretch of time without a drink. As winter came, Rose Mary called him and persuaded him to come back to the city to be with her; he resumed drinking as soon as he returned (Walls, 2005).

In order to assess family functioning, clinicians may interview all or some family members or ask patients about how the family functions. Some clinicians and researchers try to assess family functioning more systematically than through interviews or observations. One tool for doing so is the *Family Environment Scale* (Moos & Moos, 1986), which requires family members to answer a set of questions. Their answers are integrated to create a profile of the family environment—how the family is organized, different types of control and conflict, family values, and emotional expressiveness. Such information helps the clinician or researcher to understand the patient within the context of his or her family and identifies possible areas of family functioning that could be improved (Ross & Hill, 2004). Another family assessment tool that focuses on family functioning is the *Family Adaptability and Cohesion Scales, Version 3* (Olson et al., 1985), which consists of 20 questions about family adaptability and cohesion that are answered by one or more family members.

Researchers have studied families in which one member has a particular type of disorder and compared these findings to those from families without such a member (Cook-Darzens et al., 2005). For example, in one Chinese study, researchers gave versions of both the Family Environment Scale and the Family Adaptability and Cohesion Scales to families that had a member with schizophrenia and families that had no member with schizophrenia. Families with a member with schizophrenia had more conflict and were less cohesive (Phillips et al., 1998). As with other assessment tools, however, an individual's or a family's data should be compared to norms of people from similar cultural backgrounds.

Note that the presence of certain distinctive characteristics in families with a member who has a psychological disorder does not necessarily indicate that these characteristics *caused* the disorder; it is possible that something about the affected family member (such as particularly intense symptoms of his or her disorder or some other characteristic) elicits certain types of behavior from other members of the family. So, for instance, families with a member who has schizophrenia may be less cohesive because the ill family member's symptoms and ensuing family stress lead other members to seek support from friendships. That is, the ill member's symptoms may decrease family cohesion, not the other way around. Thus, the assessed family environment may contribute toward, or be a product of, the family member's illness—or the family environment and the member's illness may both reflect other factors, such as living in extreme poverty.

Community

When making a clinical assessment, the clinician should try to learn about the patient's community in order to understand what normal functioning is in that environment. As we saw in Chapter 2, people who have low socioeconomic status (SES) are more likely to have psychological disorders. Those people live in poorer communities, which tend to have relatively high crime rates—and so they are more likely to witness a crime, be a victim of crime, or to live in fear. What, then, is “normal” functioning in this context?

In an effort to understand a patient within his or her social environment, “community” may be defined loosely—it can refer not only to where the patient lives, but also to where he or she spends a lot of time, such as school or the workplace. Some jobs and work settings can be particularly stressful or challenging, and a comprehensive assessment should take such information about a patient into account. Consider that some work settings place very high demands on employees—high enough that some may become “burned out” (Aziz, 2004; Lindblom et al., 2006). Symptoms of burnout (a psychological condition, though not a psychological disorder in DSM-IV-TR) include feeling chronically mentally and physically tired, dissatisfied, and performing inefficiently—which resemble symptoms of depression (Maslach, 2003; Mausner-Dorsch & Eaton, 2000).

In some cases, such as when determining whether an elderly patient whose memory is deteriorating is able to continue living at home alone, a thorough assessment may require the participation of a wide range of people in the patient's community (Gilmour, Gibson, & Campbell, 2003). The patient's medical doctor, neighbors, relatives, and community-based elder services coordinator may each contribute vital information to the assessment.

The clinician should also assess the patient's capacity to manage daily life in his or her community, considering factors such as whether the patient's psychological problems interfere with the sources for social support and ability to communicate his or her needs and interact with others in a relatively normal way. Similarly, the clinician may be asked to determine whether the patient would benefit from training to enhance his or her social skills (Combs et al., 2008).

Culture

To assess someone's reports of distress or impairment, a clinician must understand the person's culture. Different cultures have different views about complaining or describing symptoms, which influence the amount and type of symptoms people will report to a mental health clinician—which, in turn, can affect the diagnosis a clinician makes. For instance, compared to white British teenagers with anorexia nervosa, who say they are afraid of becoming fat and report being preoccupied with their weight (both symptoms are part of the criteria set for anorexia), British teenagers of South Asian background do not report these symptoms, but are more likely to report a loss of appetite (Tareen,

Getty Images

Clinicians should inquire about the problems and strengths of a patient's community, such as the presence of violence and the sources for support. Such information helps us understand the wider context of the patient's symptoms, as well as interventions that might be helpful.

Hodes, & Rangel, 2005). Thus, the reported symptoms of the British teenagers of South Asian background may not meet enough of the criteria for a diagnosis of anorexia (although they may still have significant distress, impairment, or risk of harm).

Such cultural differences may underlie, at least in part, the dramatic differences in the apparent rates of serious mental illness across countries, shown in Figure 3.4 (WHO World Mental Health Survey Consortium, 2004). (A mental illness was considered *serious* if the individual was unable to carry out his or her normal activities for at least 30 days in the past year.) These rates were based on data gathered in face-to-face interviews. Notice how much higher the rates are in the United States compared to other developed and developing countries. One explanation for this discrepancy is that Americans are less inhibited about telling strangers about their psychological problems. People in other countries might have minimized the frequency or severity of their symptoms.

Figure 3.4

3.4 ▸ Rates of Serious Mental Illness Across Countries From 2001 to 2003, the World Health Organization conducted surveys to measure the prevalence of serious mental disorders in the populations of various countries. The results revealed significant differences among countries (WHO World Mental Health Survey Consortium, 2004).

Assessment as an Interactive Process

Mental health researchers and clinicians learn about patients from assessing psychological and social factors and, to a lesser extent, neurological and other biological factors. Information about each type of factor should not be considered in isolation, but rather should influence how the clinician understands the other types of information.

Knowledge of psychological factors must be developed in the context of the patient's culture. Psychiatrist Paul Linde (2002) recounts his experiences working in a psychiatric unit in Zimbabwe: The residents of that country generally understand that bacteria can cause an illness such as pneumonia, but they nonetheless wonder why the bacteria struck a particular individual at a specific point in time

(a question that contemporary science is just beginning to try to answer). They look to ancestral spirits for an answer to such a question, even when a particular person is beset with mental rather than physical symptoms. A first experience of hallucinations and delusions may signal the beginning of a long and chronic course of schizophrenia, or it may be a one-time occurrence brought on in part by extreme stress or severe substance intoxication. In the latter case in Zimbabwe, the hallucinations and delusions are viewed as signs that the individual is being called to become a healer, a *n'anga*, and not as indicators of mental illness.

Thus, knowledge of the patient's culture influences how an outside researcher such as Linde understands the symptoms. When a patient in Zimbabwe claims to be hearing voices of dead ancestors, Linde undoubtedly interprets this symptom somewhat differently than he would if a white, American-born patient made the same claim. At the same time, knowledge of a patient's family history of chronic schizophrenia (which may indicate a neurological factor—genetic, in this case) will also influence the interpretation of the patient's symptoms. Thus, assessment of each type of factor can influence the assessment of the other types.

However, comprehensive assessment of all three factors in the same patient is extremely costly and rarely undertaken. Formal testing beyond a brief questionnaire that the patient completes independently can be relatively expensive, and often health insurance companies will not pay for routine assessments; they will pay only for specific assessment procedures or tests that they have authorized in advance, based on indications of clear need (Eisman et al., 2000). Beyond an interview, other forms of assessment are most likely to occur as part of a legal proceeding (e.g., custody hearing or sentencing determination) or as part of a research project related to psychological disorders and their treatment.

Key Concepts and Facts About Assessing Psychological Disorders

- An assessment may be performed in order to obtain additional information for a diagnosis, monitor the course of symptoms, determine what type of treatment might be most beneficial, or monitor the progress of treatment.
- Assessment tools and techniques must be reliable and valid, and clinicians should take care to compare a patient's assessment data to an appropriate norm for the patient's background.
- Neurological and other biological factors may be assessed with various methods. Neuroimaging techniques can assess brain structure (X-rays, computerized axial tomography, and magnetic resonance imaging) and brain function (positron emission tomography and functional magnetic resonance imaging). Neurotransmitter levels can be assessed through magnetic resonance spectroscopy, and neurotransmitter and hormone by-products can be measured in blood, urine, and cerebrospinal fluid. Neuropsychological testing can assess brain functioning.
- Various methods are used to assess psychological factors. These include the clinical interview (unstructured, structured, or semistructured), observing the patient (e.g., appearance and behavior), the patient's self-report, and the reports of others involved in the patient's life. Each method has advantages and limitations. Specific aspects of psychological functioning can be assessed through tests of cognitive abilities and personality functioning can be assessed with inventories, questionnaires, and projective tests.
- Some techniques used to assess psychological factors (such as interviews and questionnaires) also can be used to assess social factors—such as family functioning—as well as to provide a more detailed portrait of the patient's community and culture. These social factors affect, and are affected by, neurological and psychological factors.

Diagnosing and Assessing Rose Mary and Rex Walls

Now that you know something about diagnosis and assessment, let's review what we know—and what we don't know—about the Rose Mary and Rex Walls, starting with Rex. We know that he drank alcohol—regularly and to excess. In fact,

he drank so much and so chronically that when he stopped drinking he developed *delirium tremens* (also known as the DTs)—withdrawal symptoms marked by hallucinations and shaking. He clearly would have been diagnosed as having *alcohol dependence* (disorders related to the abuse of and dependence on alcohol and other substances are discussed in Chapter 9).

We don't know whether the tall tales he told about himself were delusions or merely attempts to make himself look good in his own eyes and those of other people. Based on Jeannette's descriptions of her father, it appears that Rex also strove to be the center of attention. This pattern of self-centered behavior suggests that he may have had a personality disorder (specifically, what is known as *narcissistic personality disorder*, discussed in Chapter 13). Several other personality disorders might also be appropriate diagnoses, including *paranoid personality disorder*, given his frequent statements about the FBI and unions being after him or against him, and *antisocial personality disorder*, given his frequent disregard for the rights and safety of others—including his wife and children—and his clear violation of the law (at one time he created and carried out a scheme to defraud banks). Given his long history of drinking, though, it is hard to sort out how much of his behavior arose from the effects of alcohol dependence and how much might have been caused by an underlying personality disorder. However, the vast majority of people who abuse or are dependent on alcohol do not develop Rex's other problems—and thus it's not likely that his alcoholism can account for these other problems.

What about Rose Mary? Based on Jeannette's descriptions of her mother's difficulties with work—her lack of motivation to work despite the family's dire circumstances, her difficulty getting out of bed in the morning in order to get to work, and her inability to complete her school-related paperwork without assistance—Rose Mary may have suffered from depression. It is possible, though, that these behaviors instead may have been expressions of anger and resentment about feeling forced to work when her husband was so irresponsible. She was bitter that she hadn't become a famous artist and blamed her lack of success on her children. In addition, given her own preoccupations with her worth as an artist, even as her children were starving, she may well have had *narcissistic personality disorder*.

However, again we need to be cautious: No mental health clinician can know with certainty what, if any, specific disorder Rose Mary or Rex Walls may have had. We cannot make a direct clinical assessment of neurological, psychological, or social factors; we can only infer such factors from their daughter's account, which does not provide the kind of information needed to make an accurate clinical assessment.

Clinicians and researchers diagnosing and assessing patients should keep in mind the possibility that symptoms of a psychological disorder can arise from medical problems. These medical problems can range from a brain tumor, stroke, or hormone imbalance to a condition like anemia, the symptoms of which may overlap with those of depression. For Rose Mary and Rex Walls, it's possible that malnutrition (and for Rex, the effects of chronic heavy drinking) adversely affected their psychological functioning. Therefore, patients should obtain appropriate medical evaluations to ensure that their psychological symptoms are not caused by a medical problem. Only after ruling out medical illnesses can the mental health clinician or researcher have confidence in a diagnosis of a psychological disorder.

SUMMING UP

Summary of Diagnosing Psychological Disorders

Among other purposes, classification systems for diagnosis allow: (1) patients to be able to put a name to their experiences and to learn that they are not alone; (2) clinicians to distinguish “normal” from “abnormal” psychological functioning and to group together similar types of problems; and (3) researchers to discover the etiology, course, and success of treatments for abnormal psychological functioning.

Classification systems also have drawbacks. They can be subject to diagnostic bias—perhaps on the basis of the patient’s sex, race, or ethnicity. Classification systems should be both reliable and valid. Reliability is less likely when the criteria for disorders are not clear and when the criteria for different disorders significantly overlap.

The most commonly used classification system in the United States is the *Diagnostic and Statistical Manual of Mental Disorders*, presently in its 4th edition, text revision (DSM-IV-TR). The DSM-IV-TR: (1) generally does not focus on etiology (the causes of disorders), but focuses instead on what can be observed rather than inferred; and (2) lists explicit criteria for each disorder and includes a system for clinicians and researchers to record diagnoses as well as additional information that may affect diagnosis, prognosis, and treatment.

DSM-IV-TR has been criticized on numerous grounds, including the subjectivity of some of the criteria of some disorders, the categorical nature of the classification system, and the large number of disorders contained in it.

Psychological disorders are primarily diagnosed by clinical and counseling psychologists, psychiatrists, psychiatric nurses, and social workers. Each type of clinician has received somewhat different training and therefore may gather different types of information and use that information in different ways.

Thinking like a clinician

Your abnormal psychology class watches a videotape of a clinical interview with Peter, a man who has been diagnosed with schizophrenia. Your professor has been researching new criteria for diagnosing schizophrenia and has asked you and your classmates to determine whether Peter does, in fact, have schizophrenia according to the new criteria. If you and your classmates disagree with each other about his diagnosis, what might that indicate about the criteria’s reliability and validity, and what might it indicate about the interview itself?

The professor then asks you to decide whether Peter has schizophrenia as defined by

the DSM-IV-TR criteria. What are some of the advantages and disadvantages of using DSM-IV-TR? Based on what you have read, what factors, other than the specifics of Peter’s symptoms, might influence your assessment? (*Hint:* Think of biases.) Should Peter be diagnosed with schizophrenia, might there be any benefits to him that come with the diagnosis, based on what you have read? What might be the possible disadvantages for Peter of being diagnosed with schizophrenia? Be specific in your answers.

Summary of Assessing Psychological Disorders

An assessment may be performed in order to: (1) obtain additional information for a diagnosis, (2) monitor the course of symptoms, (3) determine what type of treatment might be most beneficial, or (4) monitor the progress of treatment. Assessment tools and techniques must be reliable and valid, and clinicians should take care to compare a patient’s assessment data to an appropriate norm for the patient’s background.

Neurological (and other biological) factors may be assessed with various methods. Neuroimaging techniques can assess brain structure (X-rays, computerized axial tomography, and magnetic resonance imaging) and brain function (positron emission tomography and functional magnetic resonance imaging). Neurotransmitter levels can be assessed through magnetic resonance spectroscopy, and neurotransmitter and hormone by-products can be measured in blood, urine, and cerebrospinal fluid. Neuropsychological testing can assess brain functioning.

Various methods are used to assess psychological factors. These include the clinical interview, observing the patient, the patient’s self-report, and the reports of others involved in the patient’s life. Each method has advantages and limitations. Specific aspects of psychological functioning can be assessed through tests of cognitive abilities and personality functioning can be assessed with inventories, questionnaires, and projective tests.

Some techniques used to assess psychological factors can also be used to assess social factors—such as family functioning—as well as to provide a more detailed portrait of the patient’s community and culture. These social factors affect, and are affected by, neurological and psychological factors.

Thinking like a clinician

Suppose that you have decided to become a mental health professional. What type of

training (and what type of degree) would you obtain and why?

Now suppose that you are working in an emergency room, assessing possible mental illness in patients. You have been asked to determine whether a 55-year-old woman, who was brought in by her son, has a psychological disorder severe enough for her to be hospitalized. Based on what you have read, if you could use only one assessment method of each type (neurological, psychological, and social), what methods would you pick and why?

Diagram of a simple flower

Foundations of Treatment

Leon is a 45-year-old postal employee who was evaluated at a clinic. He claims to have felt constantly depressed since the first grade, without a period of ‘normal’ mood for more than a few days at a time. His depression has been accompanied by lethargy, little or no interest or pleasure in anything, trouble concentrating, and feelings of inadequacy, pessimism, and resentment. His only periods of normal mood occur when he is home alone, listening to music or watching TV.

“On further questioning, Leon reveals that he cannot ever remember feeling comfortable socially. Even before kindergarten, if he was asked to speak in front of a group of his parents’ friends, his mind would ‘go blank.’ He felt overwhelming anxiety at children’s social functions, such as birthday parties, which he either avoided or, if he went, attended in total silence. He could answer questions in class only if he wrote down the answers in advance; even then, he frequently mumbled and couldn’t get the answer out. He met new children with his eyes lowered, fearing their scrutiny, expecting to feel humiliated and embarrassed. He was convinced that everyone around him thought he was ‘dumb’ or ‘a jerk.’

“As he grew up, Leon had a couple of neighborhood playmates, but he never had a ‘best friend.’ His school grades were good, but suffered when oral classroom participation was expected. As a teenager, he was terrified of girls, and to this day he has never gone on a date or even asked a girl for a date. This bothers him, although he is so often depressed that he feels he has little energy or interest in dating.

“Leon attended college and did well for a while, then dropped out as his grades slipped. He remained very self-conscious and ‘terrified’ of meeting strangers. He had trouble finding a job because he was unable to answer questions in interviews. He worked at a few jobs for which only a written test was required. He passed a civil service exam at age 24 and was offered a job in the post office on the evening shift. He enjoyed this job as it involved little contact with others. He was offered several promotions but refused them because he feared the social pressures. Although by now he supervises a number of employees, he still finds it difficult to give instructions, even to people he has known for years. He has no friends and avoids all invitations to socialize with co-workers. . . . Leon has never experienced sudden anxiety or a panic attack in social situations or at other times. Rather, his anxiety gradually builds to a constant high level in anticipation of social situations.” (Spitzer et al., 2002, pp. 124–125)

Chapter Outline

Treatments That Target Neurological Factors

- Medications that Change Brain Functioning
- Changing Brain Function Through Brain Stimulation
- Biofeedback
- Changing Brain Structure Through Neurosurgery
- Targeting Neurological Factors in Younger and Older Populations

Treatments That Target Psychological Factors

- Psychodynamic Therapy
- Client-Centered Therapy
- Cognitive-Behavior Therapy
- Incorporating Technology Into Treatment
- Targeting Psychological Factors in Younger and Older Populations

Treatments That Target Social Factors

- Interpersonal Therapy
- Family and Systems Therapy
- Group Therapy
- Community-Based Treatment
- Targeting Social Factors in Younger and Older Populations
- Treating a Multicultural Population
- Finances and Managed Care

Creating a Treatment Plan

- Choosing a Specific Treatment
- Choosing One or More Treatments

Treatment (for psychological disorders)

The use of a procedure or substance to reduce or eliminate psychological problems or symptoms of psychological disorders and/or improve quality of life.

Biomedical treatments

Treatments that are designed to reduce target symptoms and/or improve quality of life by changing brain functioning, hormonal activity, or another aspect of bodily functioning.

Psychopharmacology

The use of medication to reduce or eradicate symptoms of psychological disorders; also the study of such treatment.

Agonists

Medications that mimic the effects of a neurotransmitter or neuromodulator and activate a particular type of receptor.

A clinician might consider many different types of treatment for Leon's depression and anxiety, depending both on Leon's specific symptoms and on the type of treatment the clinician is trained to provide. **Treatment** for psychological disorders is the use of a procedure or substance to reduce or eliminate psychological problems or symptoms and/or improve quality of life.

Notice that the definition of *treatment* does not explicitly mention abnormality. In fact, many people who seek treatment do not have symptoms that warrant a DSM-IV-TR diagnosis. They have problems in their relationships or work or are struggling with a personal issue; they simply want to talk things through and receive guidance and support. Because these sorts of problems are not "abnormal," such people, and their treatment, are not specifically discussed in this book.

As our definition implies, treatment has two possible goals: (1) to reduce or eliminate specific symptoms, and/or (2) to improve the general quality of life. With regard to the first goal, successful treatment may reduce or eliminate *some* symptoms, but not necessarily all of them. A given treatment focuses on diminishing particular symptoms, referred to as the *target symptoms*. For instance, in treating Leon's social anxiety, medications may target the physical symptoms of anxiety (such as an increased heart rate when he thinks he must talk to others). Cognitive techniques may target unrealistic and maladaptive thoughts about social interactions ("I will be totally humiliated if I try to talk to someone at work"). Behavioral techniques may target the physical symptoms as well as the avoidant behavior. Each type of treatment targets specific symptoms, either by addressing the symptoms directly (for example, by using behavioral techniques) or by altering the factors that give rise to the symptoms (for example, changing the levels of neurotransmitter substances). A given type of treatment may improve certain symptoms but not others.

What about the second goal of treatment? Treatment may also seek to improve the *quality of life*—patients' psychological, social, and material well-being (Gladis et al., 1999). Researchers and clinicians recognize that health is not simply the absence of disease, but is a state of having mental and social well-being (World Health Organization, 1948). Research examining how treatment improves patients' quality of life asks whether their relationships with friends, relatives, and coworkers have improved, whether the patients can take better care of themselves, and whether they can function more fully in society (Abraham et al., 2006; Beasley et al., 2006; Keyes, 2007).

Generally, clinicians who are trained to diagnose psychological disorders (see Chapter 3) are also trained to treat such disorders. Mental health treatment may take place in hospitals, psychiatric institutions, clinics, private offices, religious institutions, or, less frequently, in patients' homes or workplaces. Who provides a particular patient's treatment and where it is provided

depend on that patient's health insurance coverage and finances, the availability of appropriate treatment within the patient's community, and possibly the patient's ability to travel in order to obtain specialized treatment.

One way to categorize the treatments themselves is according to the type of factor they target: neurological, psychological, or social (see Table 4.1). But ultimately, all treatments have the same broad goal—to decrease symptoms and/or improve quality of life. The goal of treatment can be likened to an X on a map—the place toward which the treatment nudges the patient; each type of treatment provides a different path toward that destination. Different treatments, when successful, bring the patient to the same general place, but follow different paths.

Table 4.1 ► Aspects of Neurological, Psychological, and Social Factors That May Change as a Result of Successful Treatment

Neurological Factors	Psychological Factors	Social Factors
<ul style="list-style-type: none"> • Neuronal activity • Levels of transmitter substances • Level of stress hormones • Amount of substance used (for those with substance abuse) • Bodily symptoms of arousal (as in anxiety disorders or sexual disorders) • Appetite • Sleep 	<ul style="list-style-type: none"> • Mental processes • Mental contents • Specific behaviors, including those associated with caring for oneself • The experience and regulation of emotions 	<ul style="list-style-type: none"> • Relationships (social support, pattern of family and work interactions) • Social isolation • Socioeconomic status

Although a given treatment targets a particular factor or set of factors, the treatment also creates feedback loops among factors: As some symptoms are reduced or quality of life improves, these changes in turn affect additional factors, other than those directly targeted. A rising tide raises all boats. Throughout this book, we highlight sections that discuss these treatment-initiated feedback loops by placing in the margin our feedback loop icon, along with an arrow pointing to the type of factor that is being directly targeted by the treatment. For instance, suppose that medication (which directly targets a neurological factor) successfully treated Leon's social phobia so that he was able to interact with people more freely (social factor) and not be anxious beforehand or ruminate about it afterward (psychological factor). Because social situations would no longer fill him with dread, he would in turn be less aroused in such situations (neurological factor).

Let's review the most common methods of treatment, considering them in terms of the type of factor that is each treatment's primary target.

Treatments That Target Neurological Factors

One way to treat Leon's depression and anxiety would be to make neurological factors the direct target of treatment. **Biomedical treatments** reduce target symptoms and/or improve quality of life by changing brain functioning, hormonal activity (which is regulated by the brain), or another aspect of bodily functioning (which typically is also regulated by the brain; see Table 4.1). Thus, the general goal of these treatments is to change neurological functioning directly in some way; as we shall discuss, several different methods can achieve this goal.

Medications that Change Brain Functioning

Throughout the ages and across cultures, healers have treated abnormal thoughts (mental processes and mental contents), feelings (affect), and behaviors by dispensing medicines to sufferers. Using medication to reduce or eradicate symptoms of psychological disorders, and the study of such treatment, is termed **psychopharmacology**. Medications that affect mental process or mental contents, affect, or behavior are called *psychotropic* medications. Psychotropic medication is most frequently administered as pills, but can also be administered via skin patches (which allow it to be absorbed through the skin), or by injection.

Goals of Medication

Medications generally are intended to affect neurological factors (such as overarousal in anxiety disorders) or psychological factors (such as thoughts, feelings, and behaviors related to depression) by increasing or decreasing specific types of brain activity; that is, medications cause particular sets of neurons to fire more or less than they otherwise would.

The key point about successful treatment with medication is that the beneficial effects go beyond altering brain activity—the changes in brain activity, in turn, influence psychological factors (mental processes, mental contents, affect, and behavior) and social factors (interactions with family members, friends, and coworkers). These positive psychosocial changes in turn influence neurological and other biological processes.

Methods of Medication

Medication can alter neural activity in several ways. Figure 4.1 on the next page shows a *synapse*—the space between the sending neuron's terminal button and the receiving neuron's dendrite—and the various methods by which medications can alter neuronal activity. Medications can alter activity in the synapse by:

- mimicking the effects of a neurotransmitter or a neuromodulator, thereby activating a particular type of receptor; such medications are called **agonists**.

Keith Philpott/Time Life Pictures/Getty Images

By definition, biomedical treatments target neurological factors, but such treatments also affect other sorts of factors. In particular, the relationship between the patient and the person providing the treatment is itself an intervention that addresses social factors: The patient receives support, advice, and, at least some of the time, the feeling that someone cares. Biomedical treatments—like any type of treatment—also address psychological factors by giving the patient hope and a framework for understanding his or her symptoms and problems.

4.1 ► Using Medication to Change

Brain Functioning Medications can alter events at the synapse, and thereby change brain functioning. A medication can (a) mimic the effects of a neurotransmitter substance (that is, act as an agonist); (b) bind to receptors and thereby prevent neurotransmitter molecules from binding (that is, act as an antagonist); (c) cause extra amounts of a neurotransmitter to be released from the terminal button into the synapse; or (d) partially block reuptake of leftover neurotransmitter molecules in the synaptic cleft (that is, act as a reuptake inhibitor). Drugs can also alter the level or activity of other substances that are produced in glial cells that surround a synapse, which in turn influence the amount of neurotransmitter in the synaptic cleft.

Figure 4.1

Antagonists

Medications that bind to a receptor site on a dendrite (or cell body) and prevent the neurotransmitter in the synapse from binding to that receptor or cause less of it to bind.

- binding to a receptor site, which prevents the neurotransmitter in the synapse from binding to the receptor (or causes less of it to bind); such medications are called **antagonists**.
- causing the release of extra amounts of a neurotransmitter from the terminal button into the synapse.
- increasing or decreasing the level or activity of other substances that activate or inactivate a neurotransmitter.

- partially blocking *reuptake* (the process by which neurotransmitter molecules left in the synapse are reabsorbed into the terminal button to be recycled for later use), thereby increasing the amount of neurotransmitter in the synaptic cleft. Such medications are referred to as **reuptake inhibitors**.

Just as imbalances of different neurotransmitters are associated with different symptoms (see Chapter 2), different medications affect the various neurotransmitters differently, which changes synaptic activity among only some sets of neurons. That is, medications are *selective* in their effects. For instance, *selective serotonin-reuptake inhibitors* (SSRIs, such as Prozac, Zoloft, and Celexa, taken for depression or anxiety) affect serotonin activity. Similarly, *noradrenaline reuptake inhibitors* (such as Strattera, taken for attention-deficit/hyperactivity disorder) affect noradrenaline (also called norepinephrine) activity.

As more is learned about brain systems and neurotransmitters, researchers are able to develop new medications to target symptoms more effectively and with fewer side effects. Thus, for any given disorder, the number of medication options is likely to increase over time. Next, we'll take a brief look at the medications used to treat key disorders. When we discuss specific disorders in later chapters, we will address medications for treating them in more detail.

Schizophrenia

Mental health clinicians most commonly treat schizophrenia and other psychotic disorders with a class of medications referred to as **antipsychotic medications** (or *neuroleptic medications*); these medications reduce certain psychotic symptoms, such as hallucinations. However, they do not cure the disorder. The original, or traditional, antipsychotics include Haldol and Thorazine. A newer group of antipsychotics, called *second-generation antipsychotics* or *atypical antipsychotics*, may reduce additional symptoms such as withdrawal, apathy, and lack of interest and improve cognitive functioning (Keefe et al., 1999). However, as we will discuss in Chapter 12, research has shown that atypical antipsychotics are not necessarily superior to traditional antipsychotics (Green, 2007; Kahn et al., 2008; Keefe et al., 2006). Both traditional and a typical antipsychotics affect the neurotransmitter dopamine, along with other neurotransmitters, and can have considerable side effects (such as significant weight gain).

Depression

Depression is often treated with SSRIs, SNRIs, *tricyclic antidepressants* (TCAs), or *monoamine oxidase inhibitors* (MAOIs). TCAs have been used since the 1950s, and until SSRIs were available, were the most commonly used type of medication to treat depression. MAOIs have the drawback of possibly causing potentially fatal changes in blood pressure if the person taking them eats food that contains tyramine (a substance found in cheese and wine). These medications may also be prescribed for other types of disorders, such as various anxiety disorders or eating disorders (Rosenbaum et al., 2005).

Anxiety Disorders

For the long-term treatment of anxiety disorders, antidepressants such as tricyclics, SSRIs, or SNRIs can be effective (Rosenbaum et al., 2005). The optimal dosage for treating anxiety symptoms generally differs from the optimal dosage for treating depression (Gorman & Kent, 1999; Kasper & Resinger, 2001; Rivas-Vazquez,

Reuptake inhibitors

Medications that partially block the process by which a neurotransmitter is reabsorbed into the terminal button, thus increasing the amount of the neurotransmitter in the synaptic cleft.

Antipsychotic medications

Medications that reduce certain psychotic symptoms; also called *neuroleptic medications*.

Medications, particularly antidepressants, are prescribed for an ever widening range of conditions. By 2008, 11% of female Americans and 5% of male Americans were taking antidepressants (Barber, 2008). Medications have helped many people, but should personality traits (such as shyness or grouchiness) long considered to be in the normal range be treated with medication?

Benzodiazepines

A class of medications commonly known as tranquilizers.

Electroconvulsive therapy (ECT)

A procedure that causes a controlled brain seizure in an effort to reduce or eliminate the symptoms of certain psychological disorders.

Transcranial magnetic stimulation (TMS)

A procedure that sends sequences of short, strong magnetic pulses into the cerebral cortex via a coil placed on the scalp.

Transcranial magnetic stimulation is a new technique that might treat some kinds of depression more effectively than ECT.

AP Photo/Charles Krupa

2001). For short-term treatment of anxiety symptoms, psychiatrists may prescribe **benzodiazepines** (commonly referred to as *tranquilizers*) such as Valium or Xanax.

Changing Brain Function Through Brain Stimulation

Medication changes brain functioning through a circuitous route: The medication is generally swallowed, then absorbed into the bloodstream, and ultimately transported to the particular synapses. Two other biomedical techniques can change patients' brain functioning more directly: electroconvulsive therapy and transcranial magnetic stimulation. The former has been in use for many years, and thus much is known about who might or might not benefit from it; the latter is relatively new, and so guidelines about its use are only beginning to be formulated.

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is a procedure that causes a controlled brain seizure in an effort to reduce or eliminate the symptoms of certain psychological disorders. An electric current is passed through the head via electrodes that are placed on the scalp. The current causes a seizure. Just before ECT treatment, the patient receives a muscle relaxant, and the treatment occurs while the patient is under anesthesia. Because of the risks associated with anesthesia, ECT is performed in a hospital and may require a hospital stay. A typical course of ECT can involve six to twelve sessions over several weeks, with about three sessions per week. Some patients report memory loss for events that transpired before the ECT treatments (Kho, Van Vreeswijk, & Murre, 2006).

Researchers do not yet understand why ECT is effective in treating depression. In the 1940s and 1950s, ECT was a major neurological treatment, but was used less often after effective medications were developed. ECT became politically unpopular when the public discovered that the procedure was sometimes used to make troublesome patients docile. Moreover, some patients reported cognitive difficulties as a result of ECT. Today, the cognitive impairments and other side effects of ECT have been significantly reduced, and laws prevent ECT from being used simply to calm unruly patients. Given these improvements, the use of ECT to alleviate severe and treatment-resistant depression—the disorder for which this procedure is most effective—has increased since the 1980s (Glass, 2001), and now is administered to about 12.5 per 100,000 people in the general U.S. population. ECT is more commonly used for older adults than younger adults (Rapoport, Mamdani, & Herrmann, 2006). It is also used more frequently for wealthy patients than for those in publicly funded hospitals, perhaps in reaction to the fact that ECT was previously overused in such hospitals (Sackeim, Devanand, & Nobler, 1995).

Transcranial Magnetic Stimulation

In contrast to ECT, which transmits electrical impulses, **transcranial magnetic stimulation (TMS)** sends sequences of short, strong magnetic pulses into the cerebral cortex via a coil placed on the scalp. Each pulse lasts only 100–200 microseconds. TMS has varying effects on the brain, depending on the exact location of the coil and the frequency of the pulses, and researchers are still working to understand how the magnetic field affects brain chemistry and brain activity (George, Lisanby, & Sackheim, 1999).

Studies indicate that TMS can be used effectively to treat depressed people for whom medication has not helped (Bretlau et al., 2008), and it may work as well as ECT (Avery et al., 2006; Dannon et al., 2002; Rosa et al., 2006). In 2008, the U.S. Food and Drug Administration approved TMS as a treatment for depression that should be used after traditional treatments have failed.

Other studies have suggested that TMS may reduce symptoms that arise in a variety of disorders, not only in depression (Alonso et al., 2001; Grisaru et al.,

1998; Hoffman et al., 2005). Additional studies are needed to confirm these experimental results and determine the optimal location of the coil, as well as the frequency and strength of the pulses, for treating each disorder.

TMS offers several advantages over ECT: It produces minimal side effects and is easier to administer (no anesthesia or hospitalization is needed). In fact, the most commonly reported short-term side effect, a slight headache, affects only about 5–20% of those receiving TMS.

Although ECT and TMS can provide relief for some disorders, these direct methods of brain stimulation are generally used only when other types of treatment have been unsuccessful.

Biofeedback

Biofeedback is a technique by which a person is trained to bring normally involuntary or unconscious bodily activity, such as heart rate or muscle tension, under voluntary control. It works as follows: Electrical leads are placed on the body in the appropriate locations to measure the targeted biological activity (such as pulse rate or muscle tension level), and the patient can see the activity (displayed on a graph or as a sequence of flashing lights) or hear it (in the form of musical tones or beeps transmitted through headphones or a speaker). At first, patients can only slightly affect the biological activity, but over time—largely by a process of trial-and-error—each patient discovers his or her own way to induce the desired change. When the person does something that produces a desired change, this feedback serves as a positive reinforcer—which makes it more likely that the person will repeat that behavior to produce that change in the future. With training, a patient eventually can learn to keep the targeted biological activity within the desired range (Blanchard, 2000). Biofeedback is used to treat involuntary muscle tension associated with some anxiety disorders and some sexual disorders (Chapters 7 and 11; Reiner, 2008).

Will & Deni McIntyre/Photo Researchers

Biofeedback is designed to allow patients to control biological activity that is normally involuntary. Successful use of biofeedback draws on learning principles. This woman is learning to identify and decrease muscle tension.

Changing Brain Structure Through Neurosurgery

Neurosurgery—brain surgery—is used only rarely to treat people with symptoms of psychological disorders. It is a treatment of last resort, used when all other treatments have failed and the disorder is sufficiently severe that it prevents even a semblance of normal life (Davidovsky, Fleta, & Moreno, 2007; Morgan & Crisp, 2000; Price et al., 2001). During neurosurgery, either specific brain structures are destroyed or their connections with other parts of the brains are severed, thereby changing brain functioning; these changes in brain functioning in turn reduce the intensity or frequency of the symptoms. For example, neurosurgery can be a last resort treatment for obsessive-compulsive disorder (OCD), a disorder in which individuals are extremely preoccupied with performing mental rituals, such as counting to 100 after having a self-defined “bad thought,” or physical rituals, such as repeatedly going back to check that the door is locked after leaving home. Such rituals can be repeated for hours at a time. For patients with extremely severe symptoms of OCD, when all else has failed, neurosurgery may be used to destroy a small part of the anterior cingulate cortex. This procedure can disrupt the brain circuit that keeps patients engaged in their mental or physical ritual (Jenike, Baer, & Minichiello, 1998).

Biofeedback

A technique by which a person is trained to bring normally involuntary or unconscious bodily activity, such as heart rate or muscle tension, under voluntary control.

Targeting Neurological Factors in Younger and Older Populations

Patients at two ends of the developmental continuum—children (including adolescents) and the elderly—may respond somewhat differently than do young and middle-aged adults to the same biomedical treatments. Let's explore how biomedical treatments may be modified for these special populations.

Targeting Neurological Factors in Younger Patients

The Food and Drug Administration is the federal agency in the United States charged with determining whether a medication is safe for use and, if so, for what disorders and at what dosages. However, most medications are tested on and approved for use with adults. (One exception is the skin patch containing a daily dose of *methlyphenidate* for the treatment of attention-deficit/hyperactivity disorder.) However, some medications that are effective for adults may not alleviate symptoms in children; for example, tricyclic antidepressants are not an effective treatment for depression in children (Stein, Weizman, & Bloch, 2006). Other medications are prescribed for patients *off-label*, meaning that the medication has not been approved for treating the given disorder or for treating children and/or adolescents. For younger patients, the dosage and frequency of medications that are prescribed off-label may need to be adjusted, and these patients may need to be monitored for adverse side effects more frequently than are adults.

Electroconvulsive therapy has rarely been used to treat children and adolescents, and so there isn't much research to guide clinicians about what kind of disorders and symptoms are appropriate to treat with ECT in younger patients and what level of electric current is best (Sporn & Lisanby, 2006). Interest in using brain stimulation techniques to treat children and adolescents is increasing because side effects of various antidepressant medications, such as increased risk for suicide, have been noted in young patients (Stein et al., 2006).

Targeting Neurological Factors in Older Patients

As adults become older, their bodies, and certain cognitive functions, change—although in most cases these changes do not significantly interfere with normal functioning. For instance, older adults tend to process information more slowly (Salthouse, 2005) and may have difficulty remembering names of objects or people (Nicholas et al., 1985). In addition to these cognitive changes among the elderly, their symptoms of some disorders may be different; for example, depressed elders tend to have more agitation and more memory problems than do depressed younger adults (Segal, Pearson, & Thase, 2003).

Mental health clinicians who treat older adults should be prepared to modify biomedical treatments for this population. Consider that older adults are typically more sensitive to medications and so need lower dosages than do younger adults (Fick et al., 2003). In fact, if older adults are given a dose that is standard for younger adults, they may experience symptoms that mimic psychological disorders—such as being sedated (which can cause them to be slower, both physically and cognitively) and confused.

In addition, many elderly people take medications to treat physical problems, and these medications can adversely affect their mood, cognitive functioning, or behavior. Indeed, one study found that elders who do not live in institutional care (such as nursing homes) take an average of five prescription medications each day (Rajska-Neumann & Wieczorowska-Tobis, 2007). Such medications, or their interactions, can cause symptoms that appear to be related to depression, such as difficulty concentrating, sedation, and confusion. Thus, an elderly patient may *appear* to be depressed, but not actually be.

When older people actually are depressed, electroconvulsive therapy is often markedly more effective than it is for younger people. In addition, older depressed patients may be more likely to receive ECT because they may experience more side effects of antidepressant medication and so not be able to stay on the medication long enough—and at a high enough dosage—for their depression to lift (Rabheru, 2001).

Of all the biomedical treatments presented in this section, the most appropriate treatment for Leon's depression and anxiety would be medication. ECT or TMS would not be considered appropriate because Leon's depressive symptoms don't seem severe enough. Biofeedback is not a treatment for depression. Surgery is much too drastic for Leon's problems, even if it were certain that surgery could cure depression or anxiety (which it cannot, at least not at present). However, some of the treatments that target psychological and social factors (discussed in subsequent sections) are likely to be as effective as medication for treating depression and anxiety—if not more so. Further, the positive effects of treatments that target psychological and social factors often continue after the treatment ends. In contrast, even if medication were effective for Leon's depression and anxiety, his symptoms would probably return after he stopped taking the medication.

Key Concepts and Facts About Treatments That Target Neurological Factors

- The goal of treatment is to reduce or eliminate problems or symptoms and/or to improve quality of life. Various procedures and substances are used to treat psychological disorders.
- Treatments that target neurological factors, sometimes referred to as biomedical treatments, include medications, brain stimulation (electroconvulsive therapy and transcranial magnetic stimulation), biofeedback, and, in rare cases, neurosurgery.
- Medications can alter synaptic activity by:
 - mimicking the effects of a neurotransmitter or a neuromodulator (agonists);
 - binding to a receptor site, which prevents the neurotransmitter in the synapse from binding to the receptor or causes less of it to bind (antagonists);
 - causing the release of extra amounts of a neurotransmitter from the terminal button into the synapse;
 - increasing or decreasing the level or activity of other substances that activate or inactivate a neurotransmitter; or
 - partially blocking reuptake of a neurotransmitter from the synapse.
- Electroconvulsive therapy (ECT) induces a controlled brain seizure by passing current through electrodes on the scalp; this treatment is performed in a hospital, under anesthesia, and usually involves up to a dozen sessions over several weeks. ECT is most effective for treating severe depression.
- Transcranial magnetic stimulation (TMS) delivers very brief magnetic pulses into the cerebral cortex. TMS is approved as a treatment for depression when other treatments have failed. Unlike ECT, TMS does not require anesthesia (and so need not be administered in a hospital), and it has fewer side effects.
- Biofeedback is a technique by which patients can bring involuntary bodily activity, such as heart rate or muscle tension, under voluntary control. Biofeedback training sessions require the patient to monitor the targeted bodily activity and, through trial and error, discover how to modify this activity.
- Neurosurgery, usually considered a treatment of last resort, is sometimes used to modify brain structures that contribute to severe disorders in cases where other treatments have not been effective.
- Biomedical treatments used with adults may need to be modified for use with children or elderly patients.

Treatments That Target Psychological Factors

Many of the types of treatments that might be most appropriate for Leon's depression and anxiety are *psychosocial* therapies or treatments—treatments that target psychological factors or social factors. Treatments that target psychological factors specifically focus on mental processes, mental contents, affect, and behaviors (see Table 4.1). A variety of treatments directly target psychological

factors; we'll consider psychodynamic therapy, client-centered therapy, and cognitive-behavior therapy. These treatments differ in the specific psychological factors that they target, their goals, and the methods used. However, when successful, all of these treatments affect mental processes, mental contents, affect, and behaviors.

Psychodynamic Therapy

Sigmund Freud's psychoanalytic theory (see Chapter 1) radically changed conceptions of how psychological problems arise and how best to treat those problems. Freud promoted *psychic determinism*, the theory that all behavior, no matter how minor (except for biological functions), has underlying psychological causes. In particular, he believed that the unconscious contains drives and urges concerning sex and aggression, and the individual's behaviors are responses to those unconscious drives or urges. Such drives arise from the id, one of three psychic structures of the mind. The drives are restrained and regulated by the superego, which houses the internalized morals of society and the family. And the ego mediates among the id, the superego, and the constraints of reality.

Freud held that psychological problems arise in large part from conflicts among the urges of the id and from the regulatory actions of the superego and ego. Rather than treating such problems medically—with medications or medical procedures, as was done in Europe at the end of the 19th century—Freud treated patients by having them talk about their problems and trying to discern the unconscious causes of the problems.

The Goals of Psychoanalysis and Psychodynamic Therapy

Psychoanalysis refers to the intensive psychotherapy based on Freud's view that psychopathology arises from unconscious conflict. The ultimate goal of psychoanalysis is to help patients manage impulses and urges more adaptively. To attain this end, the patient tries to: (1) understand the events in his or her past (especially interactions with his or her parents), and (2) understand how those events and his or her unconscious urges influence current difficulties. The theory holds that once patients become aware of the unconscious urges that are creating problems, they will be capable of more adaptively handling impulses arising from those urges. That is, when patients have attained sufficient *insight* into their problems, they can make more satisfying and productive choices; insight, according to proponents of psychodynamic therapy, is the main catalyst of change.

Psychoanalysis is time-consuming and expensive (and rarely covered by health insurance plans). Patients meet with their *psychoanalyst* (a therapist who provides psychoanalysis) four or five times per week, and the average patient participates in 835 sessions over at least 4 years (Voth & Orth, 1973). Psychoanalysis is difficult to study scientifically because each patient receives a unique course of treatment (tailored to his or her own personal issues) over a long period of time. Nevertheless, the available studies have not usually found this treatment to be effective for many disorders. Psychoanalysis is less common today than in previous decades because of the time and cost involved and its uncertain benefits.

The more common treatment that is based on psychoanalysis is **psychodynamic therapy**, which involves less frequent sessions, less emphasis on aggressive and sexual drives, and more attention to present experiences (in contrast to psychoanalysis's focus on past experiences). Very brief forms of this less intensive treatment can consist of as few as 12 to 20 sessions (Bloom, 1997; Malan, 1976; Sifneos, 1992). Table 4.2 outlines the major differences between psychoanalysis and psychodynamic therapy.

Both psychoanalysis and psychodynamic therapy are designed to help patients understand that their unconscious motivations influence their behavior in specific ways and to help them make better choices. According to Freud, however, such treatment is not a cure, but a method for transforming deep misery into mundane unhappiness.

Psychoanalysis

The intensive psychotherapy based on Freud's view that psychopathology arises from unconscious conflict.

Psychodynamic therapy

A form of psychotherapy based on psychoanalysis but that involves less frequent sessions, less emphasis on aggressive and sexual drives, and more attention to present experiences.

Table 4.2 ▶ Differences Between Psychoanalysis and Psychodynamic Therapy

	Psychoanalysis	Psychodynamic Therapy
Frequency	Four or five times a week	Usually not more than twice a week
Duration	Years, or indefinitely	A few years or less
Seating Arrangements	Patient lies on a couch; the analyst sits behind the patient, off to the side, out of the patient's view.	Patient and therapist both sit on chairs, facing each other.
Emphasis	More emphasis on sexual and aggressive urges and childhood experiences	Less emphasis on sexual and aggressive urges; more emphasis on current—rather than past—experiences

David Young-Wolff/Photo Edit

Methods of Psychodynamic Therapy

Freud and his followers developed a variety of techniques to allow the analyst and patient to glimpse the workings of the patient's unconscious and to promote insight.

The Therapeutic Alliance

Both psychoanalysis and psychodynamic therapy emphasize the importance of a **therapeutic alliance**, the positive relationship between the therapist and the patient (Greenberg & Mitchell, 1983; Klein, 1932; Kohut, 1977; Sullivan, 1953; Winnicott, 1958). This patient-therapist collaboration, a social factor, provides the trust and good will needed to undertake the challenging work of the therapy. The therapeutic alliance also can supply patients with a *corrective emotional experience*, an opportunity to work through past unresolved experiences in a safe environment with the therapist (Alexander & French, 1946). This experience can lead to improvements in symptoms, personality, and behavior.

Free Association

One method that Freud developed in order to determine patients' unconscious conflicts is **free association**, in which patients report aloud their train of thought, uncensored. Psychodynamic therapists believe that the content and pattern of patients' unedited thoughts reveal unconscious urges and responses to those urges.

Interpretation

Free association is usually used in conjunction with **interpretation**, in which the therapist infers the unconscious meaning or motivation behind a patient's words and behaviors and shares this inference with the patient. Thus, the therapist might first note a patient's thought pattern during free association and then point out possible unconscious meaning in the patient's associations. The therapist also uses interpretation when a patient makes a speech error, such as saying "father" instead of "bother"; such errors are thought to be laden with meaning and are often called *Freudian slips*. According to Freud, interpretation should help the patient become aware of his or her unconscious conflicts. The patient's own interpretations are not generally considered as accurate as the therapist's because the patient's unconscious urges and conflicts are presumed to make him or her less objective.

Dream Analysis

Another method that Freud developed to plumb a patient's unconscious is **dream analysis**, in which the therapist interprets the content of a patient's dreams. Freud

Therapeutic alliance

The positive relationship between the therapist and the patient.

Free association

The psychodynamic technique in which patients report aloud their train of thought, uncensored.

Interpretation

The psychodynamic technique in which the therapist infers the unconscious meaning or motivation behind a patient's words and behaviors and shares these inferences with the patient.

Dream analysis

The psychodynamic technique in which the therapist interprets the content of a patient's dreams.

Psychoanalysts and psychodynamic therapists interpret unconscious meaning from patients' slips of the tongue, referred to as *Freudian slips*.

Sidney Harris/ArtistMarket.com

called dreams the “royal road to the unconscious” (1900/1958) and proposed that dreams have both:

- a *manifest content*, which is the content of the dream itself, as recounted by the patient (such as a nightmare that Leon might have about standing in front of a group of people who are laughing at him); and
- a *latent content*, which is the hidden, true meaning expressed by the unconscious.

In dream analysis, the therapist carefully examines the dream’s manifest content in order to infer its latent content. A psychodynamic therapist might infer that Leon’s nightmare expressed a reaction to his own aggressive urges. In other words, in his nightmare, Leon’s wish to hurt others was transformed (via the process of reaction formation—see Chapter 1) into his being hurt by their laughter.

Using Resistance

At some point during psychodynamic therapy, patients are likely—overtly or covertly, consciously or unconsciously—to hinder treatment; such behavior is referred to as *resistance*. Patients may come late to therapy sessions (or forget to come at all) or refuse to free associate, to discuss a dream, or to answer the therapist’s questions. Resistance is most likely to arise when disturbing or painful memories or thoughts come into consciousness. Rather than viewing resistance as a problem, the psychodynamic therapist views it as a natural part of treatment and uses it as an opportunity to increase awareness and insight. The therapist interprets the resistance as indicating the patient’s wish to avoid certain feelings or thoughts.

Using Transference

Another inevitable part of psychodynamic therapy and psychoanalysis is **transference**, which occurs when patients interact with the therapist in the same manner that they did with their parents or other important figures in their lives. In fact, transference is an integral part of psychodynamic therapy, and the therapist encourages it by nonjudgmentally asking the patient about his or her feelings toward the therapist and encouraging the patient to explore and accept such feelings. As part of a corrective emotional experience, patient and therapist talk about the patient’s feelings toward the therapist, which serves to help the patient better understand his or her transferred feelings and how they influence his or her behavior. According to psychodynamic theory, as the patient becomes aware of such feelings, he or she is able to accept them and have more choice about how—and whether—to express them.

CASE 4.1 ► FROM THE OUTSIDE: A Patient’s Transference

A psychoanalyst describes a patient, Ms. B, and her transference:

Ms. B began her multiyear psychoanalysis when she was 29 years old, and felt she was “stagnating in my own anger.” Ms. B was passed over for advancement and thought that she might have to leave the [law] firm [where she’d worked for a number of years].

The eldest of five sisters and two brothers, Ms. B came from a middle-class neighborhood in New York City where her parents owned a “mom and pop candy store that everyone called ‘Pop’s’ because my mother was always pregnant.” She describes her mother as

Transference

The psychodynamic process by which patients interact with the therapist in the same manner that they did with their parents or other important figures in their lives.

depressed, living in fantasies, and preoccupied with having children. Ms. B's first sister (C) was born when Ms. B was 2 years old. She recalls the years following C's birth as being filled with a constant need to be with her mother and a sense of panic and rage at her mother's "unavailability." She longed for her mother's exclusive attention and would have temper tantrums when her mother could not be with her. Separation, even for a short time, was experienced as traumatic. . . .

Ms. B felt that I was an empathic and reliable person who was available to her in a special way. She also felt that I did not like her and was bored by her. When I was quiet during a session she felt I was punishing her. "Sometimes you're like my mother and sometimes my father."

As our work continued, the transference oscillated between Ms. B's view of me as being "indifferent" toward her and more interested in other female patients (particularly her "arch rival"—a patient she would see in the waiting room) and her view of me as not comforting her, not telling her that everything will be all right: "I want you to get rid of that woman . . . you're indifferent to me. Make me feel better. . . . it feels just like mother."

(Frosch, 2002, pp. 612–614)

In sum, psychoanalysis and psychodynamic therapy rely on six methods to help a patient understand his or her unconscious urges and conflicts and to promote insight and change: the therapeutic alliance, free association, interpretation, dream analysis, and the use of resistance and transference.

Client-Centered Therapy

As discussed in Chapter 1, therapists who provide treatment within the framework of humanistic psychology view psychopathology as arising from blocked personal growth. **Client-centered therapy**, a humanistic therapy developed by psychologist Carl Rogers, is intended to promote personal growth so that a client can reach his or her full potential.

The Goal of Client-Centered Therapy

Rogers believed that a client's symptoms arise from an incongruence between the *real self* (that is, the person the client knows himself or herself to be) and the *ideal self* (that is, the person he or she would like to be). This incongruence leads to a fragmented sense of self and blocks the potential for personal growth. The goal of treatment, according to Rogers, should be to decrease the incongruence, either by modifying the ideal self or by realizing that the real self is closer to the ideal self than previously thought, which in turn leads to a more integrated sense of self, and an enhanced ability for the client to reach his or her full potential. According to the theory, the client's emotional pain should diminish as the real self and the ideal self become more congruent.

Methods of Client-Centered Therapy

The two basic tenets of client-centered therapy are that the therapist should express *genuine empathy* and *unconditional positive regard* toward clients.

Genuine Empathy

The therapist does not interpret the client's words, but rather accurately reflects back the key parts of what the client said, which allows the client to experience the therapist's *genuine empathy* (Kirschenbaum & Jourdan, 2005). Were Leon in client-centered therapy, for instance, the therapist would try to convey his or her empathy for Leon's situation by paraphrasing his descriptions of his feelings and reactions to situations. According to Rogers (1951), if the therapist simply repeats the same words, reflects the client's words inaccurately, or seems to express false empathy, the therapy tends to fail.

Client-centered therapy

A humanistic therapy developed by Carl Rogers that is intended to promote personal growth so that a client can reach his or her full potential.

Behavior therapy

The form of treatment that rests on the ideas that (1) maladaptive behaviors, cognitions, and emotions stem from previous learning and (2) new learning can allow patients to develop more adaptive behaviors, cognitions, and emotions.

Cognitive therapy

The form of treatment that rests on the ideas that (1) mental contents influence feelings and behavior; (2) irrational thoughts and incorrect beliefs lead to psychological problems; and, (3) correcting such thoughts and beliefs will therefore lead to better mood and more adaptive behavior.

Cognitive-behavior therapy

The form of treatment that combines methods from cognitive and behavior therapies.

Unconditional Positive Regard

The therapist also conveys unconditional positive regard for the client, expressing positive feelings for the client, regardless of the client's expressed thoughts, emotions, and behaviors. The therapist can honestly do so by continually showing that the client is inherently worthy as a human being, distinguishing between the client as a person and the particular thoughts, feelings, and actions of the client (about which the therapist may not necessarily have a positive opinion).

According to proponents of client-centered therapy, when clients experience genuine empathy and unconditional positive regard from the therapist, they come to accept themselves *as they are*, which decreases the incongruence between real and ideal selves.

Cognitive-Behavior Therapy

Behaviorism and cognitive psychology each led to explanations for how psychopathology can arise (see Chapter 2); in turn, each of these approaches gave rise to its own form of therapy. **Behavior therapy** rests on two ideas: (1) Maladaptive behaviors, cognitions, and emotions stem from previous learning, and (2) new learning can allow patients to develop more adaptive behaviors, cognitions, and emotions. In contrast, **cognitive therapy** rests on these ideas: (1) Mental contents—in particular, conscious thoughts—influence a person's feelings and behavior; (2) irrational thoughts and incorrect beliefs contribute to mood and behavior problems; and, (3) correcting such thoughts and beliefs leads to more rational thoughts and accurate beliefs and therefore will lead to better mood and more adaptive behavior.

Although these two forms of therapy began separately, their approaches are complementary and are frequently combined; when methods from cognitive and behavior therapy are implemented in the same treatment, it is called **cognitive-behavior therapy (CBT)**. Let's look first at the unique elements of each type of therapy and then consider cognitive-behavior therapy.

The Goals of Behavior Therapy

Founded by Joseph Wolpe (1915–1997) behavior therapy is based on well-researched principles of learning (see Chapter 2). Behavior therapy stresses changing behavior rather than identifying unconscious motivations or root causes of problems (Wolpe, 1997). Behavior therapy has appealed to psychologists in part because of the ease in determining whether the treatment is effective: The patient's maladaptive behavior either changes or it doesn't.

In some cases, a behavior itself may not be immediately maladaptive, but it may be followed by unwanted consequences at a later point in time. For instance, Leon may not necessarily view avoiding social interactions as a problem, but he may worry about losing his job—a consequence—if he doesn't adequately supervise his employees because of his social anxiety. The ultimate goal is for the patient to replace problematic behaviors with more adaptive ones; the patient acquires new behaviors through classical and operant conditioning (and, to a lesser extent, modeling).

Methods of Behavior Therapy

The therapist, consulting with the patient, directs new learning; together they may focus on the *ABCs* of an unwanted behavior pattern:

- the *antecedents* of the behavior (the stimuli that trigger the behavior),
- the *behavior* itself, and
- the *consequences* of the behavior (which may reinforce the behavior).

In Leon's case, a behavioral therapist might focus on the *ABCs* of his social phobia: The behavior is Leon's avoidance of social interactions. The antecedents might include his (irrational) thoughts about what will happen if he goes into a social situation ("They will laugh at me, and I will feel humiliated"), which in turn

lead him to feel anxious. The consequences of his avoidant behavior include relief from the anticipatory anxiety.

The therapist assigns *homework*, important tasks that the patient completes between therapy sessions. Homework for Leon, for instance, might consist of his making eye contact with a coworker during the week, or even striking up a brief conversation about the weather. To prepare for this task, Leon might spend part of a therapy session practicing making eye contact or making small talk with his therapist. The success of behavior therapy is measured in terms of the change in frequency and intensity of the maladaptive behavior and the increase in adaptive behaviors.

The Role of Classical Conditioning in Behavior Therapy

As we saw with Little Albert in Chapter 2, classical conditioning can give rise to fears and phobias and, more generally, conditioned emotional responses. To treat the conditioned emotional responses that are associated with a variety of symptoms and disorders and to create new, more adaptive learning, behavioral therapists may employ classical conditioning principles.

Treating Anxiety and Avoidance A common treatment for anxiety disorders, particularly phobias, is based on the principle of **habituation**: The emotional response to a stimulus that elicits fear or anxiety is reduced by exposing the patient to the stimulus repeatedly. The technique of **exposure** involves such repeated contact with the (feared or arousing) stimulus in a controlled setting, and usually in a gradual way. The patient first creates a hierarchy of feared events, arranging them from least to most feared (see Table 4.3), and then begins the exposure process by having contact with the least-feared item on the hierarchy. With sustained exposure, the symptoms diminish within 20–30 minutes or less; that is, habituation to the fear- or anxiety-inducing stimuli occurs. Over multiple sessions, this process is repeated with items higher in the hierarchy until all items no longer elicit significant symptoms.

Exposure—and therefore habituation—to fear- or anxiety-related stimuli does not normally occur outside of therapy because people avoid the object or situation,

Table 4.3 ▶ Sample Hierarchy of Fear and Avoidance for Social Situations

If Leon constructed a hierarchy of his fears and avoidance of social situations, it might look something like this completed form. The “Fear” column contains the rating (from 0 to 100, with 100 = very intense fear) that indicates how the patient would feel if he or she were in the given situation. The “Avoidance” column contains the rating (from 0 to 100, with 100 = always avoids the situation) that indicates the degree to which the person avoids the situation. Although Leon avoids almost all the situations on the completed form, some situations arouse more fear than others.

Situation	Fear	Avoidance
Give a 1-hour formal lecture to 30 coworkers	100	100
Go out on a date	98	100
Ask a colleague to go out on a date	97	100
Attend a retirement party for a coworker who is retiring	85	100
Have a conversation with the person sitting next to me on the bus	70	100
Ask someone for directions or the time	60	99
Walk around at a crowded mall	50	98
Answer the telephone without checking caller ID	30	85

Source: Adapted from Antony & Swinson, 2000, p. 171.

Habituation

The process by which the emotional response to a stimulus that elicits fear or anxiety is reduced by exposing the patient to the stimulus repeatedly.

Exposure

The behavioral technique that involves repeated contact with a feared or arousing stimulus in a controlled setting.

thereby making exposure (and habituation) unlikely. Patients in therapy can experience exposure in three ways:

- *imaginal exposure*, which relies on forming mental images of the stimulus;
- *virtual reality exposure*, which consists of exposure to a computer-generated (often very realistic) representation of the stimulus; and
- *in vivo exposure*, which is exposure to the actual stimulus.

Leon's social phobia could be treated in any or all of these ways: He could vividly imagine interacting with others, he could use virtual reality software to have the experience of interacting with others without actually doing so, or he could interact with others in the flesh.

AP Photo/Ted S. Warren

Exposure—imaginal, in vivo, or virtual reality—can be used successfully to treat people with a variety of anxiety disorders, including a fear of heights and posttraumatic stress disorder (Krijn et al., 2004; Reger & Gahm, 2008).

Virtual reality exposure combines aspects of the other two types of exposure: As with imaginal exposure, the patient isn't actually exposed to the fear- or anxiety-producing stimulus, and, as with in vivo exposure, the patient experiences a vivid situation that isn't totally under his or her control—similar to a real situation. Virtual reality exposure has been used to treat a variety of psychological disorders, including posttraumatic stress disorder (Ready et al., 2006), even among active duty soldiers (Reger & Gahm, 2008); fear of flying (Rothbaum et al., 2006); social phobia (specifically, fear of public speaking, with a virtual audience; Anderson et al., 2005); and fear of heights (Krijn et al., 2004). Patients are less likely to refuse treatment with virtual reality exposure than with in vivo exposure (Garcia-Palacios et al., 2007). Moreover, virtual reality exposure may be more effective than in vivo exposure for some people and some disorders (Powers & Emmelkamp, 2008).

Another technique for treating fear, anxiety and avoidance is **systematic desensitization**, which is learning to become relaxed in the presence of a feared stimulus. Whereas exposure relies on habituation, systematic desensitization relies on the fact that a person cannot be relaxed and anxious at the same time. Systematic desensitization is used less frequently than exposure because it is usually not as efficient or effective; however, it may be used to treat a fear or phobia when a patient chooses not to try exposure or has tried it but was disappointed by the results.

The first step of systematic desensitization is learning to become physically relaxed through *progressive muscle relaxation*, relaxing the muscles of the body in sequence from feet to head. Once the patient has mastered this ability, the therapist helps the patient construct a hierarchy of possible experiences relating to the feared stimulus, ordering them from least to most feared, just as is done for exposure (see Figure 4.1). Over multiple therapy sessions, the patient practices becoming relaxed and then continuing to remain relaxed while imagining increasingly feared experiences.

Although systematic desensitization and biofeedback both involve relaxation, systematic desensitization uses relaxation as the first step in reducing anxiety in response to feared stimuli and does not utilize any equipment. In contrast, the goal of biofeedback is learning to control what are generally involuntary responses.

Treating Compulsive Behaviors In some cases, avoidance or fear of a specific stimulus is not the primary maladaptive behavior. For people with OCD, the maladaptive behavior is a compulsive, ritualistic action that patients feel they *must* perform in response to some stimulus. After grocery shopping, for example, a person may feel compelled to reorganize all the canned goods in the cupboard so that the contents remain in alphabetical order. Similarly, some people with bulimia nervosa feel compelled to make themselves throw up after eating even a bite of a dessert. These compulsive behaviors temporarily serve to decrease anxiety that has become part of a conditioned emotional response to a particular stimulus (e.g., randomly arranged canned goods or the sensation of dessert in the mouth).

Systematic desensitization

The behavioral technique of learning to relax in the presence of a feared stimulus.

To treat compulsive behaviors, behavior therapists may use a variant of exposure called **exposure with response prevention**, whereby the patient is carefully prevented from engaging in the usual maladaptive response after being exposed to the stimulus (Foa & Goldstein, 1978). Using this technique with someone who compulsively alphabetizes his or her canned goods, for instance, involves exposing the person to a cupboard full of canned goods arranged randomly and then, as agreed, preventing the typical maladaptive response of alphabetizing the cans. The person then habituates to the ensuing anxiety. Similarly, someone with bulimia might eat a bite or two of a dessert and, as planned, not throw up. This technique will be described more fully when we discuss treatments for OCD (Chapter 7) and bulimia nervosa (Chapter 10).

Treating Habitual Maladaptive Behaviors Some disorders—substance-related disorders, eating disorders, and sexual disorders—involve habitual maladaptive behaviors that are elicited by certain stimuli. For instance, some people drink alcohol to excess (habitual maladaptive behavior) only when they are in bars or clubs (the stimulus). Others may binge (habitual maladaptive behavior) when they eat dessert (the stimulus). Still others may become inappropriately sexually aroused (habitual maladaptive behavior) in response to touching women’s shoes (the stimulus).

To treat such disorders, the behavior therapist may seek to limit the patient’s contact with the stimulus. This technique, called **stimulus control**, involves changing the frequency of a maladaptive conditioned response by controlling the frequency or intensity of exposure to the stimulus that elicits the response. For example, the person who drinks too much in bars would refrain from going to bars; the person who binges after eating even a bit of dessert might avoid buying desserts or going into bakeries. Stimulus control will be described more fully when we discuss treatment for substance abuse (Chapter 9).

The Role of Operant Conditioning in Behavior Therapy

Whereas classical conditioning methods can be used to decrease maladaptive behaviors related to conditioned emotional responses, operant conditioning techniques can be used to modify maladaptive behaviors more generally. When operant conditioning principles such as reinforcement and punishment are used to change maladaptive behaviors, the process is called **behavior modification**.

Making Use of Reinforcement and Punishment The key to successful behavior modification is setting appropriate *response contingencies*, which are the specific consequences that follow maladaptive or desired behaviors. It is these specific consequences (namely, reinforcement or punishment) that modify an undesired behavior. The goal of behavior modification is to have someone perform a desired behavior more often or perform an undesired behavior less often (or not at all) by shifting the consequences of the behavior through reinforcement, removing reinforcement, or—less frequently—through punishment.

Some behaviors are too complex to learn or perform immediately and must be developed gradually. Let’s consider a woman who has had the eating disorder anorexia nervosa for a number of years. As we discuss in detail in Chapter 10, this eating disorder involves an inadequate intake of calories, which is a consequence of the individual’s irrational belief about being “fat.” (People with anorexia are at least 15% under their ideal weight.) When people with anorexia are in the early stages of recovery, eating a normal quantity of food can seem impossible. They may not be able to go from their daily intake of perhaps a serving of yogurt, a glass of milk, an egg white and a piece of fruit to three square meals a day along with a snack or two between meals. Sometimes the desired behavior change (in this case, resuming normal eating) can only occur gradually, and reinforcement follows small and then increasingly larger components of the desired new complex behavior. Thus, a woman recovering from anorexia nervosa might be reinforced for increasing her dinner from only a glass of milk and an apple to also include a small helping of fish. On subsequent meals, she might be expected to eat the fish (without reinforcement) and be reinforced for adding a piece of bread. This process would continue until she ate normal meals.

As part of behavioral treatment, someone with bulimia may use stimulus control initially to limit her intake of foods that she is likely to purge. If she habitually purges after eating cookies, for instance, she may want to avoid eating—or buying—cookies. Once she is out of the habit of purging, she may use exposure with response prevention to learn to eat cookies without purging.

FoodPix/lupiterimages

Exposure with response prevention

The behavioral technique in which a patient is carefully prevented from engaging in his or her usual maladaptive response after being exposed to a stimulus that usually elicits the response.

Stimulus control

The behavioral technique for changing the frequency of a maladaptive conditioned response by controlling the frequency or intensity of exposure to the stimulus that elicits the response.

Behavior modification

The use of operant conditioning principles to change maladaptive behavior.

The procedure of reinforcing a small component of behavior at a time, and then progressively adding components of changed behavior until the desired complex behavior is exhibited is called **shaping**. The process of adding components is called *successive approximation*.

Making Use of Extinction In addition to using reinforcement and punishment, therapists also rely on the principle of **extinction**, which is the process of eliminating a behavior by not reinforcing it. To see how extinction can work to change behavior, let's consider someone who has a mild version of Leon's problem of social phobia. This man only gets anxious in certain types of social situations, such as going to a party where there will be unfamiliar people. Working with a therapist, the man might realize that in the past, when his wife has suggested they go to a party, he puts up such a fuss that she doesn't push him to go—it's not worth the effort to drag him to the party and have him complain before, during, and after it. Therapist and patient might decide that the maladaptive behavior to change is his *complaining*, because it leads his wife to decline the invitation (or to leave him at home). Patient and therapist agree to have the wife come to a therapy session and propose to her that she *extinguish* her husband's complaining. That is, when he complains about parties, she should ignore these comments, and they both then go to the party. In contrast, when he talks about other things, she can respond with interest.

Keeping Track of the ABCs Through Self-Monitoring In order to determine the antecedents and consequences of maladaptive behaviors, patients often use *self-monitoring* tools, such as keeping a daily log of activities, feelings, and thoughts. By completing self-monitoring logs like the one in Figure 4.2, a patient can become aware of possible *triggers*, or antecedents to a problematic behavior. The date, day of the week, and time of day can help the patient to identify triggers related to time. Information about the context can help the patient to identify whether particular situations or environments have become conditioned stimuli. Identifying thoughts, feelings, interactions with others, or other stimuli that triggered the problematic behavior (right-hand column in Figure 4.2) can help the patient and the therapist to plan the direction the therapy should take. Daily self-monitoring logs are used in treatments for anxiety, poor mood, smoking, compulsive gambling, overeating, and sleep problems, among others.

Behavioral techniques that rely on operant conditioning principles are often used in inpatient psychiatric units, where clinicians can intensively monitor and treat patients 24 hours a day, 7 days a week. Under these conditions, caregivers can change the response contingencies for desired and undesired behavior. In order to change behavior, treatment programs for psychiatric patients, mentally retarded children and adults, and prison inmates often employ **secondary reinforcers**, objects and events that do not directly satisfy a biological need but are desirable nonetheless. Examples of secondary reinforcers are praise or the opportunity to enjoy a favorite activity, such as watching television or using a computer. In addition, a common form of secondary reinforcement relies on a system in which participants can earn a "token" or chit by engaging in desired behaviors. The tokens or chits can be exchanged at a "store" for small items such as candy or for privileges such as permission to go out for a walk. A treatment program that uses such secondary reinforcers to change behavior is called a **token economy**.

The Goals of Cognitive Therapy

Unlike behavior therapy, cognitive therapy focuses not on what can be directly observed (stimuli, responses, and consequences of responses), but rather on internal states and events—namely, on the way people perceive and interpret objects and events can influence their mental health. In particular, many individuals with psychological disorders have automatic but irrational thoughts or incorrect beliefs that were formed as a result of past experiences. Such dysfunctional thoughts and beliefs, in turn, contribute to maladaptive behaviors and poor mood. Cognitive therapy is designed to modify the automatic thoughts and beliefs that contribute to psychological disorders.

Shaping

The process of reinforcing a small component of behavior at a time and then progressively adding components until the desired complex behavior occurs.

Extinction

The process of eliminating a behavior by not reinforcing it.

Secondary reinforcers

Objects and events that do not directly satisfy a biological need but are desirable nonetheless.

Token economy

A treatment program that uses "tokens" or chits as secondary reinforcers to change behavior.

Figure 4.2

Name: <u>Leon</u>		Day: <u>Monday</u>	Date: <u>Oct 10</u>
Time of day	Problematic behavior	Context: Where the behavior occurred	What event triggered the behavior (thoughts, feelings, interactions with others)?
9 am	Avoidance: Even though I want some, I don't get coffee from cafeteria.	Sitting at desk at work, hard to fully wake up.	Wanted coffee, but worried that someone else will be in the food area and I'll feel uncomfortable around them. Then started to feel depressed and hopeless about my situation and my life.
10:15 am	Avoidance: Problem arises at work and I should talk to a colleague about it but I don't – I avoid it. I send an email instead even though that will take longer to resolve problem.	Checking over some documents at work.	Realized that a coworker made a mistake, but the thought of talking to her made me anxious. Sad and angry that I can't make this phone call.
noon	Avoidance and social isolation.	Eat my lunch at my desk rather than eat with others.	Thought about eating with others, but became anxious about their looking at me or talking to me. Then felt very sad about my life.

4.2 ► A Daily Self-Monitoring Log Leon's self-monitoring log (from a time when he worked the day shift) suggests that his depressed and hopeless feelings follow the anxiety he experiences after simply thinking about possible social interactions, which he then avoids. Treatment might focus on his social anxiety and avoidance at the outset; as those lessen, so should his depression.

Leon, for example, has irrational, dysfunctional thoughts about being evaluated, and he expects to feel embarrassed and humiliated. Thus, he avoids interacting with others. His thoughts and beliefs lead to his avoidant behaviors—and his thoughts, beliefs, and behaviors, in turn, lead to his depression. With cognitive therapy, Leon would have an opportunity to reassess whether his automatic thoughts and beliefs are realistic and, if not, learn to substitute more realistic ones that will make social interactions less anxiety-provoking. Leon should then be more likely to participate in social situations, which in turn may reduce his depression. In general, then, cognitive therapy promotes more rational and realistic thoughts and beliefs, which in turn alter the patient's behavior, which should then lead the symptoms to subside.

Rational-emotive behavior therapy (REBT)

The form of treatment in which a patient's irrational thoughts are transformed into rational ones, which in turn leads to more positive emotions and adaptive behaviors.

Methods of Cognitive Therapy

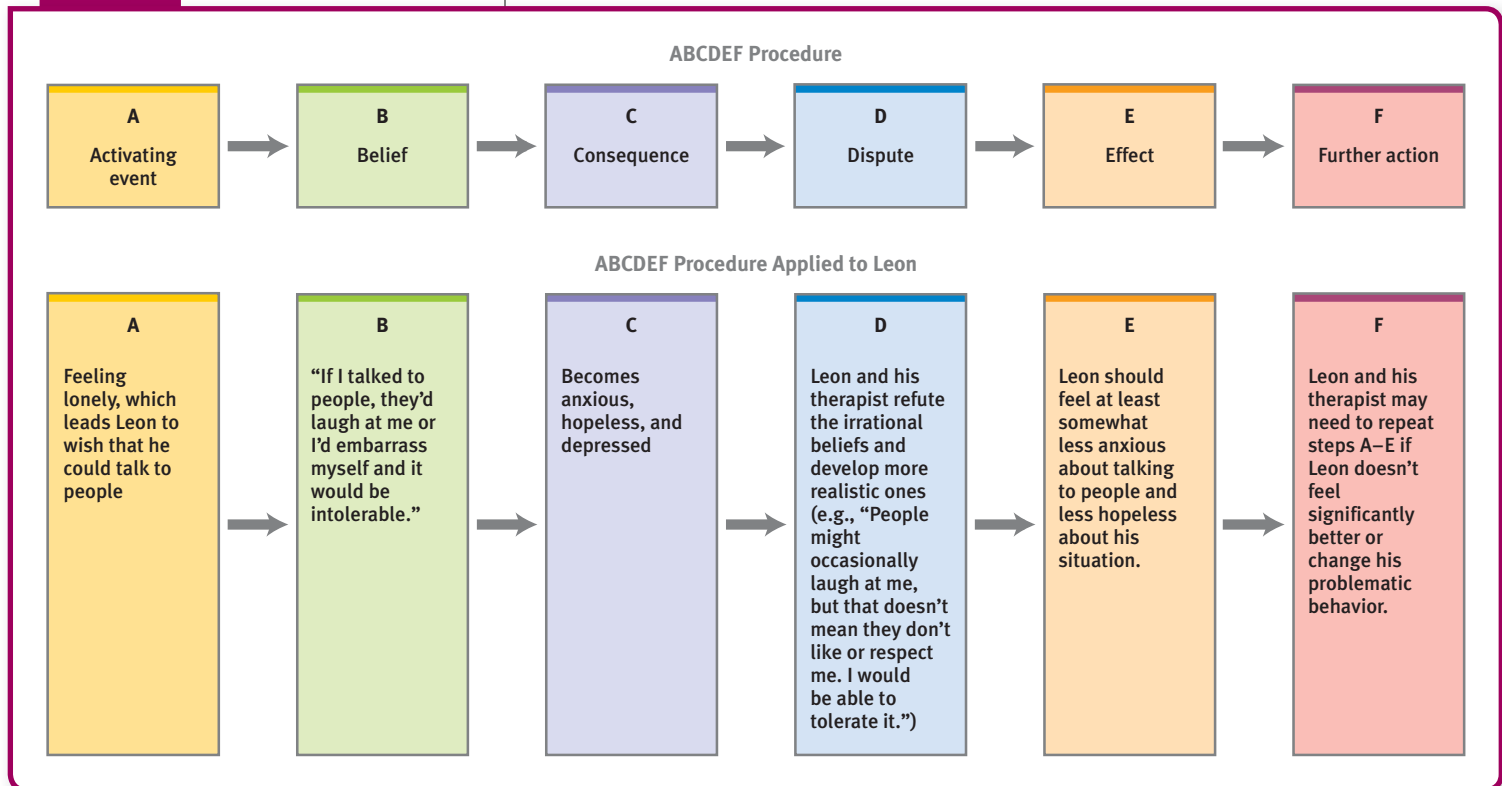

The two pioneers in the field of cognitive therapy are Albert Ellis and Aaron Beck (see Chapters 1 and 2). Although there are some differences between the specific methods these men proposed, they both placed importance on working with patients to identify and challenge irrational and illogical thoughts and on giving patients between-session homework.

Ellis's Rational Emotive Behavior Therapy

To help people counter their irrational, destructive thoughts with rational ones, Ellis developed *rational-emotive therapy*, in which the therapist challenges the patient's irrational thoughts in detail and then encourages the patient to cultivate more realistic thoughts (Hollon & Beck, 1994, 2004). Over the years, however, Ellis incorporated behavioral techniques into his therapy. His treatment is now referred to as **rational-emotive behavior therapy (REBT)**, in which a patient's irrational thoughts are transformed into rational ones, which in turn leads to more positive emotions and adaptive behaviors. At the same time, the REBT therapist tries to promote self-acceptance, so the patient comes to learn that shortcomings, errors, and failures are simply part of life rather than crimes or evidence of moral weakness. Thus, this therapy also is designed to reduce self-blame (based on faulty beliefs), which is viewed as getting in the way of rational thinking.

The REBT therapist accomplishes these goals by systematically proceeding through a sequence of observational and interventional steps that can be labeled A, B, C, D, E, and F. As shown in Figure 4.3, the series is as follows: (A) An *activating event* triggers (B) the patient's *belief*, which leads to (C) a highly charged emotional *consequence*. (Note that the event itself does not lead to the consequence; the process

Figure 4.3

4.3 ▶ The ABCDEF Procedure of Rational Emotive Behavior Therapy Rational emotive behavior therapy helps patients systematically become aware of and challenge their irrational thoughts. As patients dispute such thoughts, develop more realistic ones, and come to accept themselves more, their symptoms—such as feeling depressed—should lessen.

requires mediation through the patient's belief.) The therapist helps the patient (D) *dispute* any irrational beliefs by highlighting their destructive or illogical quality. A successful dispute leads to (E) an *effect* or an *effective new philosophy*, a new idea or a new pattern of emotion or behavior. Finally, the patient can fortify the effect through (F) *further action*.

Each REBT session is devoted to one aspect of the patient's overall problem. The patient and therapist often start a session by agreeing on the desired effect of the session's intervention. In Leon's case, the desired effect for a session might be to modify enough of his beliefs about being laughed at that he feels able to say hello to a coworker the next day. A main intervention during the dispute step involves helping the patient distinguish between a belief that something is necessary (a "must," such as "When I talk to someone, I must be suave and brilliant") and a belief that something is simply preferred ("When I talk to someone, I'd like them to think of me as suave and brilliant"). Sometimes the therapist argues with the patient as part of the dispute process. The therapist might also use role-playing to help patients develop new patterns of thinking and acting (Ellis & MacLaren, 1998).

Beck's Cognitive Restructuring

Beck's approach to cognitive therapy, like Ellis's, builds on the premise that psychological problems result from faulty automatic thoughts. Such thoughts are negative and pop into awareness without effort. For example, consider the situation of a young man, Yoshi, who, as a child, was accused by his parents of being selfish in relation to his younger brother; he grew up believing that he is a selfish person. Whenever he expresses a preference ("I'd like to see *this* movie tonight, not that one"), Yoshi feels that he is being selfish and feels bad about himself. Yoshi may live his life trying to avoid seeming selfish, and so strive to be totally flexible, never expressing preferences or desires that might conflict with those of others. His automatic thought, then, is that he is selfish; it pops into his awareness without effort.

Beck proposed that such negative thoughts arise from systematic *cognitive distortions*, which create a cognitive vulnerability—a diathesis, to use the term introduced in Chapter 1—for particular disorders (Beck, 2005). Table 4.4 shows several common cognitive distortions that lead to negative automatic thoughts.

Beck proposes that the problems created by negative automatic thoughts can diminish as the patient tests these thoughts (and discovers they are faulty) and adopts more rational and realistic thoughts. Beck developed methods to identify and reduce cognitive distortions and thereby modify automatic negative thoughts. Whereas REBT depends on the therapist's efforts to persuade patients that their beliefs are irrational, Beck's approach to cognitive therapy encourages patients to see their beliefs and automatic negative thoughts as testable hypotheses, about which they collect data. Both patient and therapist then examine the data to determine whether the patient's hypotheses are supported (or, as more often occurs, refuted). From this point of view, interactions in the world are opportunities for real-life "experiments" that can confirm, modify, or challenge the patient's beliefs (Hollon & Beck, 1994, 2004). Beck and his colleagues have developed this treatment scientifically, assessing depression, anxiety, and other problems before and after treatment; they have obtained this information in order to evaluate the degree to which the treatment works for each kind of problem, and to determine which elements cause the most positive change (Beck, 2005; Beck, Emery, & Greenberg, 2005; Beck, Freeman, & Davis, 2004; Newman et al., 2002).

This kind of cognitive therapy often relies on a patient's written self-report of each day's dysfunctional thoughts (see Figure 4.4, which shows a completed log for Leon). Patients are instructed to identify the context in which each automatic thought occurred, rate their emotional state at the time, and record the thought itself. Then they are asked to record their *rational* response to the automatic thought (which is like the dispute step in REBT) and a new rating of

Table 4.4 ► Five Common Cognitive Distortions

Cognitive Distortion	Definition	Example
Dichotomous Thinking (also called black-and-white thinking)	Maintaining only extremes of an idea, as in thinking that if you are not perfect, you are worthless	<i>“I’m trying to stop drinking and I had a beer; I blew it, so I might as well have five or six more.”</i>
Mental Filtering	Directing attention to the negative qualities of something while overlooking—or filtering out—its positive qualities	<i>Noticing only what you weren’t able to accomplish on a given day, not what you did accomplish</i>
Mind Reading	Believing that you can tell what other people are thinking, particularly what they think about you	<i>Thinking that other people are aware of what a failure you are and that they can tell that you are incompetent and detestable</i>
Catastrophic Exaggeration	Thinking that the worst possible circumstance will come to pass and that you won’t be able to handle it	<i>Fearing that people will see who you “really” are (unworthy, incompetent, unlovable) and you’ll never be able to show your face again</i>
Control Beliefs	Believing that unless you keep your life tightly under control, things will spin totally out of control and you will be permanently helpless	<i>Feeling certain that if you lose something, bad things will happen, which you won’t be able to prevent or repair</i>

their emotional state, the outcome. For example, a rational response to Yoshi’s automatic thought about being selfish might be that it is acceptable to express a strong preference sometimes, that it doesn’t necessarily indicate selfishness, and that he is often very flexible.

As shown in Figure 4.4, when a patient challenges the logic and truth of an automatic thought and then develops a rational response, it is likely that the new emotional state will be rated as less distressing. Sometimes, however, it is difficult to challenge automatic thoughts; a patient may be so accustomed to the “truth” of the automatic thought that he or she cannot perceive the thought as irrational or distorted. This would be the case if Leon were unable to see why his belief that other people will laugh at him is irrational.

The process of reorganizing how a person interprets situations and events, which relies on dysfunctional or irrational automatic thoughts with more rational ones, is called **cognitive restructuring**. The therapist helps the patient to consider the accuracy of automatic thoughts or habitual ways of interpreting himself or herself and the world and then to develop more realistic thoughts or interpretations.

Methods of Cognitive-Behavior Therapy

CBT relies in part on the methods developed by Ellis and Beck but also uses a variety of additional ones. For example, CBT therapists may also employ **psychoeducation**, which is the process of educating patients about research findings and therapy procedures relevant to their situation. The therapist may provide such information during a therapy session, may suggest a book or Web site that has relevant information, or may give the patient reading materials to take home. This new knowledge helps patients to develop a less distorted, more realistic understanding of their problems and to formulate more appropriate treatment goals (Cuijpers, 1998; Miklowitz et al., 2003; Rice & Moller, 2006).

Cognitive restructuring

The process of reorganizing how a person interprets situations and events, which relies on replacing dysfunctional or irrational automatic thoughts with more rational ones.

Psychoeducation

The process of educating patients about research findings and therapy procedures relevant to their situation.

Figure 4.4

Name: <u>Leon</u> Day: <u>Monday</u> Date: <u>Oct 10</u>				
Situation	Emotion(s)	Automatic thought(s) (ATs)	Rational response	Outcome
Actual event or stream of thoughts	Rate (1–100%)	ATs that preceded emotion. Rate of belief in ATs (1–100%)	Write rational response to ATs. Rate belief in rational response (1–100%)	Rerate at (1–100%)
<hr/>				
<i>I needed to talk to a colleague about a work problem.</i>	<i>Anxiety (85%)</i>	<i>If I talk with her, I will somehow be humiliated—either I will humiliate myself or she will laugh at me for reasons I won't understand. (90%)</i>	<i>It is possible I may be humiliated, but it is unlikely. Even if I do or say something inappropriate, she may not even notice or think it's stupid. (60%)</i>	<i>Anxiety (60%)</i>
<hr/>				
<i>Same situation</i>	<i>Sadness and hopelessness (70%)</i>	<i>I am so pathetic. I'm afraid to do something as trivial as talk to a colleague.</i>	<i>I may be afraid to talk to her, but I am working on my anxiety so that the next time I'll be able to do it.</i>	<i>Sadness and hopelessness (50%)</i>

4.4 ► A Daily Record of Dysfunctional Thoughts Leon's daily record can identify his train of irrational automatic thoughts and the types of events that trigger those thoughts. By countering such thoughts with rational responses, the thoughts seem less believable and the intensity of the emotions should decrease. (Format adapted from Beck et al., 1979.)

In the decades since behavior therapy and cognitive therapy emerged, clinicians and researchers have found that attempting to change both cognitions and behaviors can, for some disorders, reduce symptoms and improve quality of life more than addressing either cognitions or behaviors alone. Behavioral and cognitive approaches work together: When cognitive techniques change thoughts, changes in emotions and behaviors often follow, and when behavioral techniques change behaviors, changes in emotions, social interactions, and thoughts about oneself and the world often follow. Consider exposure therapy: The behavioral technique also challenges the cognitive distortion of catastrophic exaggeration. When patients see that horrible things do not occur upon exposure to a feared stimulus, their cognitive distortions are modified (Emmelkamp, 2004). Moreover, new cognitions may be maintained through principles of reinforcement or punishment (Roth & Fonagy, 2005).

Dialectical Behavior Therapy—CBT Plus More

CBT forms the nucleus of a relatively new type of therapy called **dialectical behavior therapy (DBT)**, which was originally developed specifically for treating people with *borderline personality disorder*, an Axis II disorder (to be discussed in detail in Chapter 13). *Dialectical* refers to the aim of helping patients to tolerate and integrate contradictory feelings, beliefs, and desires. DBT, like CBT, employs particular tools and methods to change specific thoughts, feelings, and behaviors. DBT was

Dialectical behavior therapy (DBT)

The form of treatment that includes elements of CBT as well as an emphasis on validating the patient's experience, a Zen Buddhist approach, and a dialectics component.

developed to treat people, generally women, who regularly hurt themselves physically (such as by cutting or burning themselves) or who make suicidal gestures or attempts (Linehan, 1993), and for whom other forms of therapy—including CBT—had not been successful. DBT has also been used with patients who have significant difficulty regulating their emotions and containing their impulses, such as some people with drug dependence (van den Bosch et al., 2005) and some people with bulimia nervosa (Safer, Telch, & Agras, 2001).

DBT, which generally involves individual and group therapy, includes elements of CBT, such as skills building, cognitive restructuring, and a warm and strong collaborative bond between patient and therapist. DBT adds three other components:

- *An emphasis on validating the patient's experience.* It is assumed that the patient's thoughts, feelings and behaviors in a given situation make sense in the context of his or her life, past experiences, and strengths and weaknesses. The therapist helps the patient recognize the context of the patient's experience.
- *A Zen Buddhist approach.* Patients are helped to identify and then, without judgment, accept any painful realities of their lives. Patients are encouraged to “let go” of emotional attachments that cause them suffering. Mindfulness—nonjudgmental awareness—is the goal. Patients entering DBT are often full of self-loathing and judge themselves harshly, which only serves to make them feel worse and resort to impulsive behaviors to soothe themselves; treatment is intended to reduce such unproductive judgments.
- *A dialectics component.* This therapy is a process of acknowledging and coming to terms with opposing elements—feelings, beliefs, desires. The therapist helps the patient to change what can be changed but also to accept what cannot be changed (Robins, Ivanoff, & Linehan, 2001). Patients entering DBT tend to see themselves and others in rigid all-or-nothing terms. The dialectics component helps them become less rigid in how they see themselves and others. For instance, they learn to see that most people—including themselves—can be generally good people, who sometimes make mistakes; mistakes don't necessarily indicate that people are bad or evil.

Incorporating Technology Into Treatment

In their efforts to make treatment more effective and efficient, researchers and clinicians have been inspired to incorporate technologies into treatment—usually as part of between-session work—and to broaden the ways that treatment can occur so that it need not always involve having the patient and therapist in the same room (Gega, Marks, & Mataix-Cols, 2004).

Using Technology for Between-Session Work

Patients in CBT often perform significant between-session work, such as completing self-monitoring logs, challenging their irrational or automatic thoughts, constructing hierarchies of fear and avoidance, and trying out new behaviors. Several kinds of technology can help make these between-session tasks easier to remember and to perform and can make it easier to collect and analyze the data obtained from the tasks:

- Self-monitoring is made easier with hand-held devices—such as PDAs and smartphones—or computer software. An alarm can be set to go off at programmed or random times, reminding patients to:
 - assess their thoughts, mood, and symptom level (such as anxiety);
 - perform certain mental tasks (such as coming up with a rational response to an automatic thought); or
 - perform certain physical behaviors (such as trying a relaxation technique).
- Computer software or Web sites can be used to facilitate cognitive restructuring or provide educational information or blank forms that can be completed online (Carroll et al., 2008; Eisen et al., 2008; Kurtz et al., 2007; Litz et al., 2007).

- Computer software can provide virtual reality exposure treatment, which can be particularly helpful when it would be difficult to have a therapist along for an in vivo exposure (such as on an airplane, for those with a fear of flying).

Researchers have found that 4 weeks of computer-assisted CBT treatment for anxiety plus 8 weeks of self-monitoring with a hand-held device was as effective as 12 weeks of the usual CBT (Newman et al., 1997; Przeworski & Newman, 2004).

Cybertherapy

Therapy most frequently occurs when therapist and patient are together in the same room, but technology has offered an alternative possibility—therapy at a distance. One well-established use of technology (at the low-tech end of the spectrum) is phone calls between therapists and patients for emergencies. For patients who are not able to get to a therapist's office, because they live in a rural area, are housebound with a medical illness, or because their phobias prevent a face-to-face meeting with a therapist, therapy conducted over the telephone may be better than no treatment (Ludman et al., 2007; Mohr, Hart, et al., 2005; Tate & Zabinski, 2004).

Newer technology has made possible another form of treatment that allows patient and therapist to be in different locations: **cybertherapy**, or Internet-based therapy. In such therapy, the patient and the therapist interact online. Clinicians have developed a number of different cybertherapeutic techniques (Santhiveeran & Grant, 2005):

- *E-therapy, or e-mail exchanges between patient and therapist.* Patient and therapist do not meet face to face. E-mail exchanges can be valuable to both patient and therapist in providing a real-time written record of the conversation (Murphy & Mitchell, 1998), and the task of organizing a thoughtful written communication itself can be therapeutic (Pennebaker, 1999);
- *E-mail exchanges between patient and therapist who also meet face-to-face.* Such e-mails may include updates on between-session homework assignments and questions or comments raised by a prior session (Barnett & Scheetz, 2003; Ruwaard et al., 2007).
- *Real-time chat room involving a patient and a therapist.*
- *Real-time face-to face video chats* (using webcams) between a patient and a therapist (Jerome & Zaylor, 2000).

Leon, because of his anxiety about meeting new people, might find cybertherapy initially more comfortable than face-to-face therapy. However, most therapists have reservations about using the Internet as a vehicle for therapy. Concerns about various forms of cybertherapy include (Heinlen et al., 2003):

- *Imposters.* The individual posing as a therapist may be neither professionally trained nor licensed.
- *Privacy.* With Internet or e-mail communications, confidentiality and privacy cannot be guaranteed (Young, 2005).
- *Incomplete communication.* E-mail communications lack important nonverbal cues (such as body language, facial expressions, and tone of voice); a therapist in face-to-face therapy sessions uses such information to assess a patient's problems and responses to treatment suggestions (Bloom, 1998). However, the use of webcams may reduce this concern.

Some studies have shown that treatment via cybertherapy is more effective than none at all (Lange et al., 2001; Ritterband et al., 2003), but little research so far has compared cybertherapy to in-person therapy (either in general or for specific disorders). For instance, although e-mail has been used in family therapy

AP Photo/Nati Harnik

Cybertherapy can be particularly helpful for rural or housebound patients, enabling them to meet with a therapist.

Cybertherapy
Internet-based therapy.

when a member of the family was too far away to attend sessions and with people who have severe medical problems that make it difficult to come to a therapist's office (King, Engi, & Poulos, 1998), its effectiveness in such situations has not yet been tested rigorously.

Targeting Psychological Factors in Younger and Older Populations

As when biomedical treatments are given to children and older adults, treatments that target psychological factors in these special populations may need to be modified.

Targeting Psychological Factors in Younger Patients

Many of the treatments that target psychological factors can be used with children and adolescents, although a mental health clinician may need to modify a particular method so that it is appropriate for the cognitive and emotional level of the younger patient. In addition, the clinician may ask parents to assist with between-session homework assignments. A therapist employing CBT with a child, for instance, may ask the parents to become directly involved by helping the child complete daily self-monitoring logs or by providing reinforcement in response to the child's desired behavior change.

In addition, special therapeutic methods have been developed for younger children, who may not be able to discuss their problems in detail or may have poor insight into their problems. One such method is *play therapy*, which uses toys, games, and play-based activities to elicit therapeutic change. Play therapy is used in varying ways by clinicians with different therapeutic approaches. For instance, a psychodynamic child therapist may view a child's play during a therapy session as a communication of unconscious feelings, much like free association is viewed for adults in psychodynamic therapy; the role of the clinician is then to interpret the child's play. In contrast, a cognitive-behavior therapist is likely to use play therapy to enhance a child's social and problem-solving skills; in that case, play therapy might be the medium through which modeling or role-playing occurs, where new behaviors are practiced and reinforced (Waas & Kleckler, 2000). Unfortunately, researchers have yet to evaluate whether specific uses of play therapy are effective.

Targeting Psychological Factors in Older Patients

To the extent that elderly patients have significant cognitive slowing or memory problems (or other types of impaired cognition), psychosocial treatments may need to be modified. For instance, with CBT, elderly patients may need the therapist to explain information more frequently, or they may require more opportunities to practice changing their behaviors.

In sum, we've seen that various approaches to therapy directly target psychological factors: thoughts, feelings, and behaviors. The methods of psychodynamic therapies, client-centered therapy, CBT, and DBT—and the technological innovations that can supplement such treatments—all address the psychological factors that contribute to psychological disorders.

Although in this section we have focused on psychological factors, note that the relationship between the therapist and patient is a social event: A patient's interaction with a therapist can provide support, advice, a framework for understanding symptoms and problems and the sense that someone cares. Moreover, as with all successful treatments, changing a psychological factor affects neurological factors as well as social factors: As patients more successfully regulate their emotions, think about themselves more realistically, and behave differently, their neurological functioning also changes.

Key Concepts and Facts About Treatments That Target Psychological Factors

- Psychodynamic therapy and psychoanalysis are intended to help patients more adaptively manage unconscious conflicts that arise in large part from id-driven impulses and urges. They do so by helping a patient develop insight into events in his or her past (especially interactions with parents) and how these events and unconscious forces influence current difficulties. Psychoanalysis is more time-consuming than is psychodynamic therapy.
- Psychodynamic therapy and psychoanalytic methods focus on the therapeutic alliance, and use free association, interpretation, dream analysis, resistance, and transference.
- Client-centered therapy is designed to integrate the sense of self by decreasing the incongruence between a patient's real and ideal selves. According to the theory of client-centered therapy, with an integrated sense of self comes reduced emotional pain. To accomplish these aims, therapists show the patient genuine empathy and unconditional positive regard.
- Behavioral methods often focus attention on the antecedents and consequences of a maladaptive behavior, as well as on the behavior itself. Specific methods based on classical conditioning include exposure (sometimes with response prevention), systematic desensitization, and stimulus control. Methods based on operant conditioning make use of reinforcement and punishment and may involve shaping, extinction, and self-monitoring.
- Cognitive methods based on Ellis's rational emotive behavior therapy (REBT) may follow steps (A through F) that are designed to dispute beliefs that lead to maladaptive consequences. Methods based on Beck's cognitive restructuring challenge patients' maladaptive automatic negative thoughts and encourage patients to test the accuracy of their beliefs through real-life experiments. This hypothesis testing leads patients to develop more rational responses to the automatic thoughts.
- The behavioral aspects of cognitive-behavior therapy (CBT) are intended to transform maladaptive behaviors that stem from previous learning, whereas the cognitive aspects of CBT are intended to modify irrational thoughts and incorrect beliefs that influence feelings and behavior maladaptively. Changing behaviors and thoughts in turn alters feelings as well. CBT often includes psychoeducation.
- Dialectical behavior therapy (DBT) relies on CBT methods and also has the therapist validate the patient's experience, help the patient accept and integrate contradictory feelings and thoughts, and teach the patient a Zen Buddhist approach of being nonjudgmental.
- Technology is being incorporated into treatment through the use of electronic methods for self-monitoring and cognitive restructuring. Virtual reality exposure is also sometimes used in therapy. Moreover, cybertherapy brings treatment to patients who are unable or unwilling to go to the office of a mental health clinician, and it can be a means through which patient and therapist can maintain contact between visits. However, cybertherapy has drawbacks: The therapist could be an imposter, confidential information may not remain private, and the lack of nonverbal cues for the therapist may skew the treatment in a less helpful direction.
- Treatments for children and older patients that target psychological factors may need to be modified for those populations. For instance, children may engage in play therapy (however, clinicians who have different theoretical orientations will use this method differently).

Treatments That Target Social Factors

Treatments that target social factors aim to reduce symptoms or improve quality of life by changing a person's relationships for the better and by creating, expanding, or improving a person's sense of community. Such treatments may directly or indirectly address the patient's problems. For example, when treatment that directly targets improving a family's communication leads to better family functioning, the positive change can lead to the patient's feeling more supported, which in turn can reduce symptoms. As we shall see, some treatments that target social factors would be appropriate for Leon's problems of depression and social anxiety, whereas other treatments that target social factors would be less appropriate. All these treatments have in common their focus on the patient *in the context* of other people: family members, group therapy members, coworkers, community members.

Interpersonal Therapy

Interpersonal therapy focuses on the patient's relationships and is loosely based on psychodynamic theory.

Interpersonal therapy (IPT)

The form of treatment that is intended to improve the patient's skills in relationships so that they become more satisfying.

The Goal of Interpersonal Therapy

Originally developed to treat depression, the theory underlying **interpersonal therapy (IPT)** is that symptoms of psychological disorders such as depression and bulimia nervosa become exacerbated when a patient's relationships aren't functioning well. The goal of IPT is thus to improve the patient's skills in relationships so that they become more satisfying; as relationships improve, so do the patient's thoughts and feelings, and the symptoms of psychological disorders lessen. The therapist who provides IPT tries to link specific aspects of the patient's current relationships with one of four kinds of problems in relationships (see Table 4.5; Klerman et al., 1984); each type of problem suggests a distinct goal for treatment. For example, with depressed patients, the task is to identify ways that current relationships are not satisfying and then to set about enhancing those aspects of the relationships. Perhaps a patient feels that a boyfriend does not communicate enough, and hence the patient feels a lack of intimacy; a goal in this case would be to work on ways to improve communication, which should in turn increase feelings of intimacy.

Table 4.5 ▶ Four Themes of Relationship Problems in Interpersonal Therapy

Theme	Example	Goal
Unresolved Grief	A relationship lost through death	Facilitate mourning of the lost relationship and help the patient develop other interests and activities
Role Transition	Difficulty coping with changes in life (e.g., getting a new job, having a baby, retiring) that lead to a new role for a patient or family member	Help patient develop appropriate expectations about what is needed for the new role, as well as whatever skills and social support are needed
Role Dispute	Differing expectations about an enduring relationship (such as that between coworkers, family members, or neighbors), which lead to chronic significant conflict	Help identify the particular dispute and develop ways to move forward; encourage patient to try to change patterns in the relationship or assess whether expectations are realistic
Interpersonal Deficits	Exhibiting behaviors that lead to social isolation and poor communication, such as staying in bed all day or not answering the phone	Decrease social isolation by focusing on present relationship with a therapist and forming additional relationships

Methods Used in Interpersonal Therapy

IPT was conceived of as a short-term therapy, usually lasting 16 sessions. Moreover, the therapist uses a treatment manual to guide the goals, techniques, and topics for each session to ensure that all methods of the treatment are implemented.

To achieve the goals summarized in Table 4.5, the therapist providing IPT uses a variety of methods, some borrowed from psychodynamic and cognitive behavioral therapy; these methods help patients to:

- consider the consequences of their actions in a relationship,
- role-play their interactions with significant others,
- become more aware of feelings that they have tried to ignore or push aside,
- improve their communication skills, and
- tell others how they feel in an appropriate manner (Elkin, 1994; Shea et al., 1992; Weissman, Markowitz, & Klerman, 2000).

Family and Systems Therapy

Some therapies target family functioning in order to change maladaptive patterns of interaction and to increase the support family members provide to each other.

Family Therapy

Family therapy is a treatment that involves either an entire family or some portion of a family. What constitutes a “family”? For our purposes, a *family* is any group of people that functions as a family: an extended family that includes several generations, a blended family of children and parents originally from different households, any other nontraditional family, as well as a traditional nuclear family that consists of mother, father, and their children (Carter & McGoldrick, 1999). Family therapy can be performed using any theoretical approach; the main focus is on the family, rather than an individual patient.

Systems Therapy: A Different Way of Thinking About the Family

The most prevalent theoretical orientation in family therapy is **systems therapy** (sometimes referred to as *family systems therapy*), which is designed to change the communication or behavior patterns of one or more family members. According to this approach, the family is a system that strives to maintain *homeostasis*, a state of equilibrium, so that change in one member affects other family members. Systems therapy is guided by the view that when one member changes (perhaps through therapy), change is forced on the rest of the system (Bowen, 1978; Minuchin, 1974).

To a systems therapist, the “patient” is the family, and the individual member with a psychological disorder is referred to as the *identified patient*. Systems therapy focuses on communication and power within the family. The symptoms of the identified patient are understood to be a result of that individual’s intentional or unintentional attempts to maintain or change a pattern within the family or to convey a message to family members.

The Goals of Systems Therapy

The goals of systems therapy are to identify and then change maladaptive patterns of interaction and communication among family members (Gurman, 2000). For instance, had Leon and his parents participated in systems therapy when he was younger, perhaps the therapist might have found that Leon’s parents didn’t mind the fact that Leon didn’t socialize with others; he was a good companion and having him around more meant that the parents spent less time alone as a couple. The therapist might have reframed the problem as one in which Leon needed to spend more time with others so that his parents could have more opportunities to practice spending time alone as a couple before Leon went off to college and they were alone all the time.

Methods of Systems Therapy

A systems therapist normally begins by interviewing family members about the history of the family. This interview establishes which family members are close to and distant from each other and determines how feelings, issues, and conflicts tend to be handled within the family. The systems therapist might discover, for example, that one parent is underinvolved (doesn’t interact much with his or her child, for instance), and the other is overinvolved (spending inordinate amounts of time with the child, perhaps finishing his or her sentences). In addition, the parents may have a conflicted relationship. Treatment might then focus on rectifying such imbalances in the family system. The patterns and conflicts are often illustrated graphically; Figure 4.5 illustrates an angry, antagonistic relationship between parents, which influences the child’s behavior (Kitzmann, 2000).

Family therapy

The form of treatment that involves either the family as a whole or some portion of it.

Systems therapy

The form of treatment that is designed to change the communication or behavior patterns of one or more family members in the context of the family as a whole; also known as *family systems therapy*.

Figure 4.5

4.5 ▸ Graphing the Family System

System Systems therapists may graphically illustrate the predominant family dynamic. This figure shows conflict in the parents’ relationship with each other. It also shows that each parent tries to be involved with and control the son (overfunctioning, represented by the long arrows), who has withdrawn from both parents (underfunctioning, represented by the short arrows). Part of the problem in this family system may be that the parents are constantly vying for attention from the son as an extension of their conflict with each other.

Source: Adapted from Ackerman, 1980, pp. 152, 154.

Consider an example of the methods of systems therapy in action: A mother and stepfather and the mother's two daughters from a previous marriage, Maria, age 17, and Lena, age 14, come to family therapy. Lena has taken to wearing all black and, despite her mother's clear admonition against it, has gotten tattoos and nose rings. Although she's doing okay in school, she frequently fights with her mother and her stepfather about her dress and her attitude. Lena likes her stepfather, but he and Lena's mother have been squabbling a lot for the last couple of years, and there's been a lot of tension between them, which makes Lena uncomfortable. Maria is a high school senior and is planning to go to college next year; she's just biding her time until she leaves home. During a therapy session, a systems therapist might rephrase what each family member has said in order to **validate** their experiences—demonstrate that the therapist understands each one's feelings and desires. The therapist may also try to ensure that each family member understands every other member's experience. In addition, the therapist might **reframe**—offer new ways to conceive of, or frame, the problem—in this case, Lena's behavior. Instead of viewing her behavior as a bad thing, the therapist might point out that what Lena is doing is trying to bring her mother and stepfather together by having them focus on her. If she is the focus of their negative attention, then they'll get along better with each other. The therapist might then suggest that perhaps Lena fears that if her behavior and attitude improve, the anger and tension between the mother and stepfather will increase. The therapist might praise Lena's willingness to be a lightning rod for the family tension.

Case 4.2 illustrates family systems therapy for a marital conflict.

CASE 4.2 ► FROM THE OUTSIDE: Family Systems Therapy for Depression

Ruben, a Cheyenne Native American, and his wife, Angie, a Hungarian, were at an impasse. Living on the East Coast and childless, with financial problems, they came to therapy when Ruben was offered an apprentice job with a large manufacturer, a position arranged by a member of Angie's family. Angie worked as a secretary, while Ruben held a series of temporary jobs. Instead of being happy about the new position, Ruben had become depressed and even was thinking of turning it down. Furious, Angie was threatening to leave him. . . . Angie came from a family in which women typically made decisions about work and finances, and thus helped direct the family's mobility. For her, financial stability was critical.

Ruben became depressed because he faced a major conflict. On the one hand, in his family, asking for guidance and direction through healing rituals was a way to begin to find answers to problems. Before he and Angie married, Ruben made a commitment to participate in a year-long purification ritual, both for the blessings he hoped it would bestow on his family, and to maintain his traditional ways while living as a part of the dominant American culture. Ruben felt strongly about his prior commitment to perform the ritual, and he realized that if he takes the job, he might not be able to perform the ritual as he originally intended (and thus be unable to fulfill part of his commitment to his heritage); on the other hand, his wife desired that he take the job, and he felt that the future of his marriage might be at stake if he did not take it. The goal of systems therapy was not to reduce Ruben's guilt should he not perform the Cheyenne ritual; rather, it was to help Ruben more clearly identify the conflict and his feelings, and explore acceptable ways that he could resolve the situation. This may involve helping Angie to understand the ritual and its significance to Ruben.

(Adapted from Sutton & Broken Nose, 1996, pp. 38–39)

Validate

A systems therapy technique by which the therapist demonstrates an understanding of each family member's feelings and desires.

Reframe

A systems therapy technique in which the therapist offers new ways to conceive of, or frame, the family's or identified patient's problem.

Paradoxical intention

A systems therapy technique in which the therapist suggests that the problem behavior be allowed to continue or even increase in intensity or frequency.

In certain cases, a systems therapist might employ **paradoxical intention**—by suggesting that the problem behavior be allowed to continue, or even increase in intensity or frequency. This technique is paradoxical because it seems at odds with the general goal of treatment; it is also called *prescribing the symptom* (Stanton, 1981). With Lena's family, the systems therapist might use paradoxical intention by suggesting that Lena continue to behave in ways that make her mother and

stepfather angry, at least until the adults have more practice working out their difficulties. Paradoxical intention is generally only used with families who have not otherwise made changes suggested by the therapist.

Note that systems therapy originated with therapists who worked almost exclusively with families. This history has caused systems therapy to be confused with *family therapy*. The two are not the same: Some systems therapists use a systems approach to treat only one individual, whereas some family therapists use a psychodynamic or behavioral approach rather than a systems approach.

Group Therapy

In **group therapy**, a number of patients (typically 6–8) with similar needs meet together with one or two therapists. This form of therapy can occur in a single session, in sessions that continue over years, or within some specified time limit (such as 12 weeks). Like family therapy, group therapy can be rooted in any of a variety of theoretical orientations, such as psychodynamic or cognitive-behavioral. If the therapist has a cognitive-behavioral orientation, participants in the group are likely to be assigned homework between sessions and will then discuss their homework in the group. Some therapy groups are restricted to people who have a specific problem or disorder (such as people with depression), and the group offers members psychoeducation, emotional support, or training in CBT techniques. Other therapy groups (which may be psychodynamic in approach) are open to people who are united simply by their desire to understand their relationships and to develop better ways to interact with others—romantic partners, colleagues, or other people in their lives. A psychodynamic therapist might use transference, resistance, and interpretation to help members learn about themselves and change the ways that they relate to others. In groups in which the goal is to improve interpersonal interactions, the group itself can be a forum for experimenting with new ways of interacting.

The most appropriate type of group therapy for Leon might well be one that targeted his social phobia. Just being in a group with strangers would, in and of itself, be exposure treatment for him; moreover, he might feel less alone and ashamed when hearing about other group members' similar problems and struggles.

Beyond information and support, group therapy provides interaction with others who share similar problems and goals. Hearing members talk about experiences that are similar to their own can help patients understand their own experiences more clearly and think about them in a different way. For instance, if Leon were in group therapy, after hearing about other members' experiences, he might feel less anxious being around them and realize that, just as he wasn't judging the other group members, they probably were not judging him. In turn, he might then feel more willing to be with other people. Whether group therapy helps people explore their relationships or develop skills for cognitive restructuring of automatic negative thoughts, being with other members who are struggling with the same issues decreases the sense of hopelessness, isolation, and shame that some patients feel about their problem or disorder.

Community-Based Treatment

Treatment most often occurs within a patient's community—his or her neighborhood, town, or city. Most people seeking mental health care receive **outpatient treatment**—treatment that does not involve an overnight stay in a hospital. Outpatient treatment may occur in a therapist's private office, a community mental health center or mental health clinic, an outpatient unit of a hospital, or, for those seeking pastoral counseling, within their church, synagogue, or mosque. For some people with severe symptoms, outpatient treatment consisting of weekly sessions of up to 1 hour may not be adequate, and more intensive treatment may be needed or desired. Intensive treatment may take place in a hospital, clinic, or mental health facility and may last for several hours each day or evening to 24 hours a day.

Group therapy

The form of treatment in which several patients with similar needs meet together with one or two therapists.

Outpatient treatment

Treatment that does not involve an overnight stay in a hospital.

Inpatient treatment

Treatment that occurs while a patient is in a psychiatric hospital or in a psychiatric unit of a general hospital.

Partial hospitalization

Treatment is provided at a hospital or other facility, but the patient does not sleep there.

Residential treatment

Treatment in which patients stay in a staffed facility where they sleep, eat breakfast and dinner, and perhaps take part in evening groups.

Inpatient Treatment

Inpatient treatment is the term for treatment that occurs while a patient is in a psychiatric hospital or in a psychiatric unit of a general hospital. This is the most intensive level of treatment and is provided in two main circumstances: (1) when individuals, because of a psychological disorder, are believed to be at risk of harming themselves or another person (or have already done so); and (2) when individuals do not appear able to take adequate care of themselves. The initial goals of hospitalization are to ensure the patients' safety, the safety of others, and reduce the intensity or frequency of the patients' symptoms.

Partial Hospitalization

Partial hospitalization consists of treatment provided at a hospital or other facility, but the patient does not sleep there; such treatment is more intensive than what is available through once-a-week outpatient visits, but is less intensive than the treatment received through hospitalization. Partial hospitalization is appropriate for people who are not actively dangerous to themselves or others, and such programs may last from 2 to 12 hours daily. *Day treatment programs* and *evening programs* are examples of partial hospitalization. Such programs often provide many different kinds of group therapy and teach skills for coping with symptoms such as delusions, feelings of hopelessness, or continued bingeing and vomiting. These programs also provide an opportunity for patients to discuss problems and concerns they have with specific medications, such as how to minimize side effects.

Residential Treatment

Residential treatment consists of staying in a staffed facility where patients sleep, eat breakfast and dinner, and perhaps take part in evening groups. Typically patients must go elsewhere during the day, such as to a partial hospitalization program, school, or work. Residential treatment is for people who do not need the intensity of inpatient care, but nonetheless need supervised care during the evening and night.

Self-Help

Some people choose to attend self-help groups, either as a supplement to their therapy or instead of therapy. Like group therapy, self-help groups (sometimes referred to as *support groups*) tend to focus on a particular problem or disorder. Self-help groups generally do not have a leader who is clinically trained, although a mental health professional may sometimes advise the group (Shepherd et al., 1999).

The first popular self-help program was Alcoholics Anonymous (AA), which is still widely used. AA is designed around a 12-step process of recovery from alcoholism and a belief in a "higher power" (for most participants, God), which, according to AA, is crucial to the recovery process. Most other 12-step programs, such as Narcotics Anonymous, follow this model.

There are other self-help programs that use a different approach, however, such as that of the Depression and Bipolar Support Alliance, which serves people suffering from depression or bipolar disorder and their friends and families. This program provides education about the disorders and holds groups for patients where they can learn from and support one another. Like the Depression and Bipolar Support Alliance, self-help organizations may also offer information and support groups for friends and family members (Citron, Solomon, & Draine, 1999). If a member wants the services of a mental health clinician, a self-help organization often can provide the names of therapists in the community who are experienced in treating people with a given disorder.

Like group therapy, self-help groups can diminish feelings of shame and isolation, as well as provide support and valuable information. However, sometimes the lack of a trained leader may lead to negative group interactions that go unchecked.

Much self-help does not take place in groups, but instead often relies on an individual's reading a book, listening to audio materials, or visiting Web sites. The number and variety of self-help books and materials have vastly expanded in recent years. These publications provide help for a wide variety of problems—such as depression, panic disorder, attention-deficit/hyperactivity disorder, and eating disorders—and many of the publications incorporate the theories and techniques described in this chapter. Research reveals that self-help materials are most likely to help people with depression and anxiety (Cuijpers, 1997), headache, sleep disturbances, and fears (Gould & Clum, 1993), and anxiety (Finch, Lambert, & Brown, 2000; Hirai & Clum, 2006; Scogin et al., 1990). In contrast, self-help materials have not been as successful in helping people change habits such as smoking, drinking, or overeating (Cuijpers, 1997). As you might expect, self-help materials are more likely to be helpful when people closely follow the recommended techniques (Gould & Clum, 1983).

Using self-help materials as part of therapy is sometimes called **bibliotherapy**, and therapists often advise patients to read relevant books (Campbell & Smith, 2003; Starker, 1988) in order to understand better the possible causes of their symptoms and ways to treat the disorder.

The Internet also provides a variety of self-help opportunities, including educational materials, chat rooms that serve as support groups (which may or may not be led by someone claiming to be a therapist), and interactive self-help treatments (Andersson et al., 2006; Carlbring et al., 2006). However, information can be posted online by anyone for any purpose, so online resources may not be accurate. Like some “therapists” who engage in cybertherapy, people in an online support group may be lying about their identity, may not provide accurate diagnoses, and may recommend inappropriate courses of treatment (Finn & Banach, 2000; Waldron, Lavitt, & Kelley, 2000).

Using the Internet or computer software, people can also benefit from interactive self-help programs that automatically adapt to the user's responses. These interactive programs may be more complex than a self-help book or video, but they are unlikely to surpass live therapy in terms of patient satisfaction and quality of treatment (Jacobs et al., 2001). As with cybertherapy, some online interactive self-help programs that use a cognitive-behavioral approach result in a better outcome than engaging in no treatment at all (Carlbring et al., 2006). Further research is needed, however, to assess the efficacy of these programs in comparison with live treatment.

Prevention Programs

Prevention programs are designed to prevent or inhibit the development or progression of psychological problems or disorders (Mrazek & Haggerty, 1994). The specific techniques in a prevention program might target any or all neuropsychosocial factors, but the creation of such programs relies crucially on social factors. One such program is the Big Brother/Big Sister program, which targets both psychological and social factors in children deemed at risk of developing problems because they don't have regular positive contact with an adult family member; the Big Brother or Big Sister provides such contact with an adult who serves as a mentor. Prevention programs have also been created to address suicide and drug abuse, to provide counseling for rape victims, and to provide early intervention for people who have been identified as having an elevated risk of a particular psychological disorder. This last group includes:

- those with a family history of a particular disorder,
- those who have experienced a traumatic event, and
- children whose parents have divorced.

Any treatment technique and theoretical orientation may be employed in a prevention program.

Michelle D. Bridwell/Photo Edit

For many people, self-administered treatment programs available through books and other media appear to be more effective than no treatment at all (Bilch et al., 2008; Hirai & Clum, 2006, 2008).

Bibliotherapy

The use of self-help materials as part of therapy.

Prevention programs

Programs that are designed to prevent or inhibit the development or progression of psychological problems or disorders.

Some prevention programs, such as some stress management programs, are funded privately by health insurance companies for people they insure or by corporations for their employees. Other prevention programs, such as rape crisis centers, are publicly funded and available to the public.

Many prevention programs focus on children, parents, or families with children. Although most children whose parents are divorced do not develop a mental disorder, children with divorced parents are more likely to develop a disorder than are children whose parents are not divorced. To minimize the incidence of psychological disorders in this population, some prevention programs help parents interact more effectively with their children (Pruett, Insabella, & Gustafson, 2005). These programs, at least in the short run, can diminish children's mental health problems. Such interventions target social factors (parent-child interactions) with the goal of improving or preserving the child's mental health.

For instance, consider a study by Sharlene Wolchik and colleagues (2002), which was designed to discover whether the positive effects of a prevention program for children of divorced parents continue over time (specifically, 6 years after the program) and whether having both mothers and their children involved in the program is better than having only the mothers involved. Participants were 218 families; at the time of the prevention program, the children were 9–12 years old, and the families were randomly assigned to one of three groups:

1. an 11-session “mother-only” group that received CBT. The intervention was designed to improve the mothers' relationships with their children, teach effective disciplinary methods, and reduce conflict between mothers and fathers;
2. an 11-session “mother program/child program” group that received CBT; the intervention for the mothers was the same as described above, and the intervention for the children was designed to improve their coping skills and their relationships with their mothers and to decrease their negative thoughts about the divorce and its aftereffects;
3. a control group of mothers and children who received books on adjusting to divorce.

Six years after the program, the researchers assessed psychological disorders in the children with a comprehensive computerized questionnaire, completed by the children and their parents. Results indicated that both the mother-only and the mother/child interventions helped prevent psychological disorders in those children who had more psychological problems before the intervention (more than 6 years previously); however, the fewer problems that children had at the start of the program, the less of an impact the intervention made. This makes sense because for these less symptomatic children, there was a smaller range within which the intervention could have an effect. When the two types of interventions were compared, they were found to be equally effective.

In conclusion, treatment can occur with varying intensity or frequency, depending, in part, on a patient's needs. Options include inpatient and partial hospitalization, residential treatment, outpatient treatment, or prevention programs. All of these community-based treatments target social factors—the patient in *context*. Such treatments may also target neurological and/or psychological factors. However, for a given patient, his or her health insurance company may not pay for or reimburse all types of treatment, or may limit the duration of treatment. Later, we'll examine the financial side of treatment in a bit more detail.

Targeting Social Factors in Younger and Older Populations

Treatments for children and older adults that target social factors may need to be modified for these special populations.

Targeting Social Factors in Younger Patients

As discussed in Chapter 2, all of us are influenced by factors in our social environment—and in some ways, this is particularly true of children, who are not yet able to function independently in the world and must rely heavily on the people around them. In targeting social factors, family therapy is a frequent form of treatment for children with psychological disorders. In some cases, family therapy may focus on parental guidance, instructing parents how to interact more effectively with their children; the children may not necessarily be present for all—or even any—of these discussions (Dishion & Stormshak, 2007).

Social factors may also be targeted in group therapy for children and adolescents, for instance, to help them develop appropriate social skills with peers. Other groups are for parents, to help them further develop parenting skills and make them feel less isolated. Mental health clinicians may also advise school personnel or specific teachers, to help them better understand a given child or to develop more effective ways of interacting with the child or resolving peer conflicts (Dishion & Stormshak, 2007).

Targeting Social Factors in Older Patients

Elderly patients can have psychological disorders that leave them unable to care for themselves, such as the cognitive disorder *dementia*, which involves significant memory problems (to be discussed in more detail in Chapter 15). In such cases, treatment may involve family therapy to help the patient and family members plan long-term care. The family may decide to have the elderly patient move in with a family member or into an assisted living facility. Given the medical problems that often develop or become worse with age, family therapy sessions may include members of an elder's healthcare team (Tisher & Dean, 2000).

Treating a Multicultural Population

One social factor that may not be targeted directly by a treatment may nevertheless serve as a potential backdrop to treatment, namely the demographic characteristics of the patient—ethnic background, race, or sexual orientation. The United States has an increasingly multicultural population, as shown in Figure 4.6. By the year 2025, approximately 40% of adults and almost half of all children in the United States will be from a racial or ethnic minority group (U.S. Census Bureau, 2000). Individual members of each ethnic or racial group, however, may have many different reasons for having immigrated to the United States, may have different values and traditions, and may vary in other ways that can influence treatment.

How Ethnicity Can Influence Treatment

Information about a patient's ethnic background, race, or sexual orientation can influence the type of treatment used or lead a clinician to modify the treatment. Moreover, if patient and therapist have different backgrounds, this may lead to misunderstandings about treatment goals, methods, and expectations. For instance, experiences with discrimination and prejudice can lead someone to have negative automatic thoughts about the futility of continuing to look for a better job ("What's the point, they won't hire me anyway"); the patient sees the problem (depression about feeling stuck in a dead-end, low-paying job) as having an external

Figure 4.6

cause—discriminatory hiring practices. In contrast, the therapist may see the problem as internal, in that the patient's pessimistic thinking leads the patient to behave in ways that create a self-fulfilling prophecy. In this case, patient and therapist would be working toward very different points in addressing what each perceives as the root cause of the patient's depression about finding a better job. The patient's thoughts, however, are not necessarily irrational, and if the therapist is not sensitive to that possibility and aware of how past discrimination has affected the patient's sense of self and the world, then the two of them will continue to have different goals for and expectations of treatment, possibly leading the treatment to be ineffective or the patient to drop out of treatment.

Using Mental Health Services

Although members of minority groups and Whites have similar lifetime prevalences of psychological disorders in the United States, minorities generally do not use mental health services as often as do Whites (U.S. Department of Health and Human Services, 2001). Several factors, some pragmatic, may contribute to this difference. First, members of minority groups are less likely to have health insurance coverage, which creates a financial burden on them and their families (who must pay for treatment). In addition, immigrants may not speak English well enough to communicate effectively about their psychological problems; if bilingual clinicians or translators are not available, then patients must rely on family or friends to translate for them—which can create a disincentive to seek treatment (U.S. Department of Health and Human Services, 2001). Figure 4.7 compares the proportion within each ethnic group living in the United States that is native-born versus foreign-born; the foreign-born may not be able to communicate well in English. Asian Americans and Hispanics are the ethnic groups most likely to have been born elsewhere.

Beyond these practical barriers to treatment, two additional factors may explain why minorities use mental health treatments less often than do Whites: a basic mistrust of such treatments, and the stigma of receiving treatment. Mistrust may spring in part from past experiences, in which members of minority groups may have felt disrespected or judged unfairly because of their ethnicity or race. In addition, members of minority groups may be aware of past abuses by mental health institutions and professionals—and some fear that they will be “experimented on” if they allow such institutions or professionals to have control over their fate (LaVeist et al., 2000; Neal-Barnett & Smith, 1997; U.S. Department of Health and Human Services, 2001).

Moreover, receiving mental health care may carry a stigma in some communities. Patients or family members may feel ashamed or embarrassed by the patient's problems, and hence discourage the patient from receiving treatment (Ng, 1997; Wahl, 1999). For people already experiencing discrimination, becoming a mental health patient can add another source of discrimination, making them reluctant to seek treatment. For instance, one study found that among Asian Americans, only 12% would tell a friend or family member about psychological problems, and only 4% would seek treatment from a mental health clinician; this contrasts with 25% of white Americans who would both tell friends and family and would seek mental health treatment (Zhang et al., 1998).

When minority patients do seek treatment, their symptoms tend to be more severe at the time of assessment than is typical for Whites (Snowden & Cheung 1990; Sue et al., 1991). One explanation for this finding is that some people may hope that the symptoms will disappear on their own and will consult a mental

health clinician only after the symptoms continue for a long period or become so bad as to be intolerable. In addition, some patients (and their family members) seek alternative services—for example, from a minister or traditional healer from their community—before they turn to standard mental health services; they might consult mental health clinicians only when other types of treatments have failed (Chung, 2002; Nebelkopf & Phillips, 2004).

Furthermore, minority patients are less likely to come to mental health clinicians directly; instead, they often seek treatment from their primary care physician (Snowden & Pingitore, 2002; U.S. Department of Health and Human Services, 2001). (As mentioned in Chapter 3, though, primary care physicians generally treat mental health problems less effectively than do mental health clinicians.) Compared to white patients, members of minority groups (Blacks, Latinos, and Asian Americans) prefer counseling over medication (Givens et al., 2007).

Bridging a Cultural Gap Between Patient and Clinician

Let's examine in more detail factors that mental health professionals must take into account when providing treatment and discuss ways that mental health professionals address the unique needs of different populations. (Of course, even when clinician and patient have similar backgrounds, the clinician should always try to understand the patient's unique experiences that influence the disorder and that may influence treatment and recovery.)

Research has shown that when mental health services are tailored to the needs of a specific cultural group, members of that group are more likely to make use of, and benefit from, the treatments. The term *cultural competence* refers to the ability of the mental health system and individual clinicians to provide treatment in a way that is sensitive to people from different backgrounds.

A clinician's cultural competence rests on an awareness of the biases and assumptions he or she has about mental health, mental illness, and treatment in general and in reference to particular ethnic groups; cultural competence also reflects an understanding of the different biases and assumptions held by people from other ethnic groups. The clinician and patient together develop treatment goals that respect the context in which the patient lives—family, cultural, and spiritual values, the patient's identity, cultural explanations of the psychological problems the patient is experiencing, and issues related to the relationship with the mental health clinician (Malik & Velazquez, 2002).

For instance, a Latina woman may attribute her depression to *nervios*, or nerves, whereas a clinician, hearing about a history of depression in her family, might partly attribute her depression to family-related factors (U.S. Department of Health and Human Services, 2001). Or a patient of Asian descent may frame his or her problem with depression in bodily terms rather than psychological ones. In both cases, the clinician should not dismiss the patient's views but rather should incorporate them into the treatment goals and plans that are developed with the patient.

Cultural Competence and Medication

Clinicians who prescribe medication should be aware that people from different ethnic groups may respond to medication differently than do Whites. In fact, members of different ethnic groups may metabolize drugs differently. Asian Americans and African Americans, for instance, may be more sensitive to the effects of psychotropic medications than are Whites; a standard dose for a white patient might be too high a dose for an African American or Asian American patient and would lead to

Michael Newman/Photo Edit

Therapists should be aware of cultural differences that may exist between themselves and their patients, and they should try to learn how patients' experiences of their culture influence their understanding of their problems and their goals for treatment.

more and greater side effects—which in turn might lead the patients to stop taking the medication (Lin et al., 1997; Lin & Cheung, 1999; U.S. Department of Health and Human Services, 2001). As noted earlier, Blacks generally prefer counseling to medication for psychological problems, at least in part because of concerns about side effects and how effective the medication will be (Cooper-Patrick et al., 1997). Such concerns can arise because of metabolic differences (Dwight-Johnson et al., 2000). (Note that although these findings about medication apply to groups of people, they may not necessarily apply to a given individual who is of African or Asian descent.)

Culturally Specific Treatment

Clinicians may address a patient's culture in a variety of ways, depending on the patient's facility with English and the community in which the patient lives. When immigrant patients do not speak English well, treatment should be provided by a clinician who speaks the patient's language, or who makes use of a translator. Community health centers in ethnic neighborhoods are most likely to have such resources available. In fact, such health centers may have specific programs to reach out to community members about mental health treatment and may use approaches that are consistent with the particular ethnic group's view of mental health and mental illness. Such culturally sensitive approaches result in increased use of mental health services and decreased rates of dropping out of treatment (Lau & Zane, 2000; U.S. Department of Health and Human Services, 2001), particularly among patients who are less assimilated and who do not speak English well (U.S. Department of Health and Human Services, 2001).

Cultural Sensitivity in Treatment

A therapist should not assume that a patient's different ethnic or racial background or sexual orientation will necessarily lead to misunderstandings. As long as the therapist is sensitive to *possible* differences and asks the patient about ways that his or her culture or sexual orientation may influence symptoms or treatment, the difference in backgrounds need not be a stumbling block. In fact, ethnic similarity of patient and therapist alone does not reduce the likelihood of dropping out of treatment or produce better outcomes (Ito & Maramba, 2002; Karlsson, 2005). This finding suggests that therapists can bridge most gaps that arise from different backgrounds as long as there is no significant language barrier. Case 4.3 illustrates why therapists shouldn't make assumptions about how cultural differences *must* influence treatment.

CASE 4.3 ► FROM THE OUTSIDE: Emotional or Physical Problem?

Mrs. Corrales, a 70-year-old Puerto Rican, was referred to a mental health clinic by her local priest. Mrs. Corrales had no friends within [her neighborhood]. She had migrated from Puerto Rico eight years earlier to live with her two sons and her 45-year-old single and mildly developmentally impaired daughter. Two years before she came to the clinic, her sons had moved to a nearby city in search of better jobs. Mrs. Corrales remained behind with her daughter, who spoke no English and did not work. Among other questions, the Latin American therapist asked her if she was losing weight because she had lost her appetite, to which she quipped: "No, I've lost my teeth, not my appetite! That's what irks me!" Indeed, Mrs. Corrales had almost no teeth left in her mouth. Apparently, her conversations with the priest (an American who had learned to speak Spanish during a Latin American mission and was sensitive to the losses [that people endure as the result] of migration) had centered on the emotional losses she had suffered with her sons' departure. The priest thought this was the cause of her "anxious depression." Though well meaning, he had failed to consider practical issues. Mrs. Corrales had no dental insurance, did not know any dentists, and had no financial resources.

(Falicov, 1998, p. 255)

The therapist should check with each patient to determine whether demographic differences of many kinds—in age, weight, ethnic background, country of origin, or religion, as well as race, gender, or sexual orientation—might influence treatment (Davison, 2005; Eubanks-Carter, Burckell, & Goldfried, 2005; Helms & Cook, 1999; Higgenbotham, West, & Forsyth, 1988; McGoldrick, Jordano, & Pearce, 1996; Ramirez, 1999). If such differences are salient for the patient, the therapist should inquire about the patient's relevant experiences and concerns and discuss how to shift the plans for and goals of treatment (Zane et al., 2004). For instance, Joe, a devout Catholic seeking treatment for depression related to his unhappy marriage, might explain to his Protestant therapist that, because of his religion, divorce was out of the question. Joe and his therapist could then together devise possible goals and strategies for treatment that did not conflict with Joe's religious beliefs.

Finances and Managed Care

Perhaps unfortunately, finances are another social factor that must be taken into account when treating mental illness. Mental health services make up just a small part of overall health care costs in the United States and Canada, but as the cost of providing medical care has risen significantly, external pressure to limit mental health care spending has increased. To contain costs, health insurance companies have developed a system of **managed care**, a plan that restricts access to specialized medical care by limiting benefits or reimbursement. A managed care organization tries to minimize the expense of providing health care without restricting services that it deems medically necessary. So, for instance, to keep mental health care costs down, a managed care organization might:

- restrict the number of days that a patient can remain in an inpatient unit, and will no longer pay for such treatment after that time has passed;
- restrict the mental health facilities where a patient may receive care (to those that have agreed to be paid a previously negotiated rate);
- pay for partial hospitalization rather than inpatient care;
- restrict the number of days a patient can remain in partial hospitalization; and
- limit the number of outpatient sessions or restrict the mental health clinicians whose services will be covered.

These limitations can harm patients, their families, and even society at large. In an effort to minimize the adverse effects of such restrictions, the U.S. Congress in 2008 passed the Wellstone-Domenici Mental Health Parity Act. This act requires most insurance plans to provide comparable levels of treatment benefits for mental health and physical health (as well as for substance abuse). For example, if an insurance plan does not restrict the total number of days a patient can remain in a hospital for a medical problem, it cannot restrict the total number of days a patient can remain in a hospital for a psychological disorder. Health insurers may still limit benefits—but the limitations must be equivalent for physical and mental health.

The majority of Americans who have health insurance have their mental health coverage handled through a managed care system (Open Minds, 1999). In response to managed care, therapists of every theoretical orientation have worked to maintain the same effectiveness in fewer sessions or in less intensive forms of treatment.

Some research suggests that having a time limit on psychotherapy may accelerate the rate of change for some—but not all—patients (Reynolds et al., 1996). However, patients who have complex or multiple problems are less likely to benefit from a limit on the number of sessions (Lambert & Ogles, 2004). Further research is needed to determine whether, for each psychological disorder short-term therapy can provide long-term positive change without increased rates of relapse.

Managed care

A type of health insurance plan that restricts access to specialized medical care by limiting benefits or reimbursement.

Key Concepts and Facts About Treatments That Target Social Factors

- Treatments that target social factors are designed to reduce symptoms and/or improve quality of life by changing a person's relationships for the better and by creating, expanding, or improving a person's sense of community.
- Interpersonal therapy (IPT) is intended to address a patient's problematic relationships and improve his or her interpersonal skills so that relationships become more satisfying; the theory is that as relationships improve, the symptoms of psychological disorders will lessen. IPT focuses on four themes in problems with relationships: unresolved grief, role transition, role dispute, and interpersonal deficits. The methods of IPT include focusing on the consequences of patients' actions, role-playing interactions with significant others, encouraging patients to heighten their awareness of feelings they have minimized, and helping patients to improve their communication skills.
- Family therapy can be conducted using most theoretical approaches; depending on the specific approach, the focus of family therapy may be an individual patient in the context of his or her family, or the family itself. In contrast, systems therapy views the entire family as the unit of change and is designed to improve communication or behavior patterns among family members—who may not be the identified patient—and in doing so change the system. Methods of systems therapy include validating each family member's experience, reframing the problem, and using paradoxical intention.
- Group therapy, in which several patients with similar needs meet together with one or two therapists, can be based on various theoretical approaches, such as psychodynamic therapy or CBT; the theoretical approach determines the specific methods employed.
- Treatment can occur in different settings and with differing levels of intensity, ranging from once-a-week outpatient treatment to partial hospitalization, residential treatment, and inpatient treatment. People can also receive help for psychological disorders in self-help groups and through bibliotherapy.
- Prevention programs target those at risk for a variety of psychological disorders; these interventions may focus on neurological, psychological, or social factors.
- Treatments for children and elderly patients that target social factors may need to be modified for those specific populations.
- Therapists should try to be aware of—and discuss with patients—any cultural, demographic, or other significant difference between themselves and their patients that could affect the goals and expectations of treatment or create miscommunication and misunderstanding.
- Culturally competent mental health clinicians provide treatment that is sensitive to people from different backgrounds. Mental health services that are tailored to the needs of a specific cultural or ethnic group are more likely to be used by members of that group.
- The bulk of the costs for mental health treatments are borne by health insurance programs; managed care organizations in particular may restrict treatment in an effort to minimize costs.

Creating a Treatment Plan

We've considered many different types of treatment. How does a patient and his or her mental health clinician decide on a particular course of treatment? Let's review the process of choosing one or more types of treatment for a given problem, using Leon's depression and social phobia as an example.

Choosing a Specific Treatment

How would a clinician decide what type of treatment to offer to Leon, or any other patient? The answer depends, in part, on the types of treatment the clinician has been trained to provide. For instance, in general, psychologists may be more likely to target psychological or social factors, whereas psychiatrists may be more likely to target neurological factors.

The specific treatment or treatments provided to a patient also depend on what types of treatment he or she is willing to try. Ideally, a patient has looked at reputable Web sites to learn more about his or her symptoms and the types of treatments that have been found to be effective. Leon might have developed a sense of what type of treatment he wanted to try and might have sought out a clinician who was qualified to provide that treatment.

Which types of treatment might be most appropriate for Leon's particular problems—depression and social phobia? Given that his problems did not incapacitate him or lead him to be likely to hurt himself or others, outpatient treatment

would be the most appropriate. Among the biomedical treatments, medication (most likely an SSRI) for Leon's anxiety and depression would be a reasonable place to start. Among the treatments targeting psychological factors, CBT is the one for which there is the most research support for both social phobia and depression; as we'll see in Chapter 6, though, a variety of other treatments can help alleviate depression. Among treatments targeting social factors, group therapy could be particularly helpful for Leon's social phobia—simply being in a group, whatever its theoretical orientation, would be an exposure treatment for him. The social support might also lessen his depression.

Choosing One or More Treatments

Some patients receive only one type of treatment, whereas other patients may receive more than one type—why? A given patient may receive more than one form of treatment, depending on the nature of the problem, the patient's preferences, and whether a single treatment sufficiently alleviates symptoms or improves quality of life. Moreover, constraints arising from health insurance coverage or finances can influence which treatment(s) a patient receives. Severe or chronic problems, such as schizophrenia, may be best addressed by two or more treatments, and some combined treatments may be more effective for that disorder than a particular single treatment (TADS Team, 2007). Each treatment may directly target a different factor.

Leon has two disorders: depression and social anxiety, and he might benefit from multiple treatments—one (or more) to target his depression, and one (or more) to target his social anxiety. One option would be to participate in group therapy for his social anxiety (the treatment modality of choice for that disorder) and wait to see the extent to which his depression lifts as his social anxiety diminishes. Alternatively, Leon might choose to initiate two types of treatment, one directed at his social anxiety and one at his depression. In this case, he might be in group therapy for his social anxiety and either take medication or begin CBT or another type of therapy for his depression.

Even people with one disorder may receive more than one type of treatment. For example, people with depression may benefit from a treatment that targets psychological factors while also being involved in couples therapy. Similarly, children with attention-deficit/hyperactivity disorder may take medication and also be in family therapy with their parents.

Some patients receive more than one treatment that targets the same type of factor. For instance, a depressed person may take more than one medication (targeting neurological factors), or an anxious woman might be in both couples therapy and interpersonal therapy (both targeting social factors). A given patient may initiate multiple treatments at the same time or start with one and add additional treatments as needed.

Treatments can directly target neurological, psychological, or social factors, but any successful treatment ultimately affects all three types of factors. Thus, a variety of paths can lead to the same general destination: reducing or eliminating symptoms and improving quality of life. However, as we shall see in subsequent chapters, some treatments are more effective for certain disorders than others.

Key Concepts and Facts About Creating a Treatment Plan

- The treatment or treatments given to a particular patient depend on the patient's willingness to receive particular treatments, on research results regarding specific treatments for the patient's problem, and on the expertise of the mental health clinician.
- Some patients may receive more than one type of treatment, depending on their specific problem(s), the effectiveness of a given treatment, the patient's interest in pursuing additional treatments, and the patient's insurance benefits and finances.
- Although any given treatment targets only one factor, changes brought about by an effective treatment in turn affect other factors.

SUMMING UP

Summary of Treatments That Target Neurological Factors

The goal of treatment is to reduce or eliminate problems or symptoms and/or to improve quality of life. Various procedures and substances are used to treat psychological disorders. Treatments that target neurological factors, sometimes referred to as biomedical treatments, include medications, brain stimulation, biofeedback, and, in rare cases, neurosurgery. Medications can alter synaptic activity in various ways.

Electroconvulsive therapy (ECT) induces a controlled brain seizure by passing current through electrodes on the scalp. ECT is most effective for treating severe depression. Transcranial magnetic stimulation (TMS) delivers very brief magnetic pulses into the cerebral cortex. Unlike ECT, TMS does not require anesthesia and it has fewer side effects.

Biofeedback is a technique by which patients can bring involuntary bodily activity, such as heart rate or muscle tension, under voluntary control. Neurosurgery, usually considered a treatment of last resort, is sometimes used to modify brain structures that contribute to severe disorders in cases where other treatments have not been sufficiently effective. Biomedical treatments used with adults may need to be modified for use with children or elderly patients.

Thinking like a clinician

Nita has been depressed for several weeks; although she's often teary and feels hopeless, she's able to function well enough at her job. She doesn't want to talk to a therapist about it ("I don't want any counseling or therapy"), but she's willing to see a psychiatrist for one visit ("Just to see whether there's anything that can help"). If the psychiatrist recommends a treatment that targets neurological factors, what is it likely to be and why? What would be the goal—in terms of neurological factors—of that particular type of treatment? Why would other treatments targeting neurological factors not be appropriate? What, in particular, should the psychiatrist want to know about Nita before making a recommendation?

Summary of Treatments That Target Psychological Factors

Psychodynamic therapy and psychoanalysis are intended to help each patient more adaptively manage unconscious conflicts that

arise in large part from id-driven impulses and urges. They are supposed to do so by helping the patient develop insight into events in his or her past and how these events and unconscious forces influence current difficulties.

Client-centered therapy is designed to integrate the sense of self by decreasing the incongruence between a patient's real and ideal selves. According to the theory of client-centered therapy, with an integrated sense of self comes reduced emotional pain.

Behavioral treatments use both classical and operant conditioning techniques (including habituation and extinction) to change behavior. Behavioral methods often focus attention on the antecedents and consequences of a maladaptive behavior, as well as the behavior itself.

Cognitive methods based on Ellis's rational emotive behavior therapy (REBT) are designed to dispute beliefs that lead to maladaptive consequences. Methods based on Beck's cognitive restructuring challenge patients' maladaptive automatic negative thoughts, and encourage patients to test the accuracy of their beliefs through real-life experiments.

The behavioral aspects of cognitive-behavior therapy (CBT) are intended to transform maladaptive behaviors that stem from previous learning, whereas the cognitive aspects of CBT are intended to modify irrational thoughts and incorrect beliefs that influence feelings and behavior in a maladaptive way. Changing behaviors and thoughts in turn alters feelings as well.

Technology is being incorporated into treatment through the use of electronic methods for self-monitoring, cognitive restructuring, virtual exposure, and cybertherapy. However, cybertherapy has drawbacks: The therapist could be an imposter, confidential information may not remain private, and the lack of nonverbal cues for the therapist may skew the treatment in a less helpful direction.

Thinking like a clinician

After seeing the psychiatrist, Nita decides that she definitely doesn't want anyone "messing with my brain" and will try psychotherapy instead of a neurological intervention. List the types of questions a therapist with each theoretical orientation that targets psychological factors—psychodynamic, humanist, behavioral, and cognitive—might ask of Nita. What specific types of information would each therapist want, based on his or her orientation? What techniques might each type of therapist use in treating Nita's depression?

Summary of Treatments That Target Social Factors

Treatments that target social factors are designed to reduce symptoms and/or improve quality of life by changing a person's relationships for the better and by creating, expanding, or improving a person's sense of community. Interpersonal therapy (IPT) is intended to address a patient's problematic relationships and improve his or her interpersonal skills so that relationships become more satisfying; the theory is that as relationships improve, the symptoms of psychological disorders will lessen.

Family therapy can be conducted using most theoretical approaches; depending on the specific approach, the focus of family therapy may be an individual patient in the context of his or her family, or the family itself. In contrast, systems therapy views the entire family as the unit of change and is designed to improve communication or behavior patterns among family members and in doing so change the system.

Group therapy, in which patients with similar needs meet together with one or two therapists, can be based on various theoretical approaches, such as psychodynamic therapy or CBT.

Treatment can occur in different settings and with differing levels of intensity, ranging from once-a-week outpatient treatment to partial hospitalization, residential treatment, and inpatient treatment. People can also receive help for psychological disorders in self-help groups and through bibliotherapy. Prevention programs target those at risk for a variety of psychological disorders. Treatments for children and elderly patients that target social factors may need to be modified for those specific populations.

Therapists should try to be aware of—and discuss with patients—any cultural, demographic, or other significant difference between themselves and their patients that could affect the goals and expectations of treatment or create miscommunication and misunderstanding. Mental health services that are tailored to the needs of a specific cultural or ethnic group are more likely to be used by members of that group.

Thinking like a clinician

Community Psychiatric Hospital has had its budget slashed dramatically and thus is trying to help its highest functioning inpatients move into supervised housing in the community. What are the different types of living situations that might be available? Why might the hospital want to offer group

therapy to those living outside the hospital? Some patients will live with their families; why might family therapy be offered to those families?

Summary of Creating a Treatment Plan

The treatment or treatments given to a particular patient depend on the patient's willingness to receive particular treatments, on research results regarding specific treatments for the patient's problem, and on the expertise of the mental health clinician. Some patients may receive more than one type of treatment, depending on their specific problem(s), the effectiveness of a given treatment, and the patient's interest in pursuing additional treatments. Although any given treatment targets only one factor, changes brought about by an effective treatment in turn affect other factors.

Thinking like a clinician

Now suppose that Nita, the woman with depression, is receiving CBT and taking medication. Why might she be receiving two types of treatment? What does—and doesn't—the fact that she's receiving more than one type of treatment indicate about the nature of her problem?

Researching Abnormality

Suppose you are a psychologist at a college counseling center. A student, Carlos, comes to the center because he's been depressed since his girlfriend, Liana, ended their relationship 5 weeks ago. Liana's rejection was a bolt out of the blue, as far as Carlos is concerned. He feels abandoned and alone. He has been spiraling downward since the breakup, feeling irritable and sad, sleeping a lot, and without appetite. He was just fired from his on-campus job because of his poor attitude. He doesn't care much about his classes or schoolwork. During your sessions with Carlos, he seems preoccupied with his relationship with Liana and worries that no other woman will ever love him.

Carlos is not the only student on campus to have this type of problem. You've noticed that a surprising number of students seeking help at the counseling center are depressed and have recently broken up with a boyfriend or a girlfriend. Like Carlos, these students frequently report feeling hurt, rejected, and unlovable. Some even think about suicide.

You wonder, though, whether the depression that many of these students are experiencing is a result specifically of their breakups. Perhaps they were depressed before the breakup—and that contributed to the failure of the relationship. In Carlos's case, perhaps his depression started earlier (although he hadn't realized it), and Liana got sick of his being down in the dumps. On the other hand, maybe a lot of the students would not have become depressed if their relationships had not ended.

How could you determine whether the students are depressed because their relationships ended, or whether their relationships ended because they were depressed (and this soured their relationships)? In this chapter, we explore specific methods that psychologists use to study psychopathology and its treatment, the challenges associated with the use of the different research methods, and the ways in which researchers address those challenges.

Using the Scientific Method to Understand Abnormality

Perhaps your observations about depression and relationship breakups are based simply on a coincidence: People—particularly young people—are frequently beginning and ending relationships, and

Chapter Outline

- Researching Treatments That Target Psychological Factors
- Researching Treatments That Target Social Factors
- Feedback Loops in Action: The Placebo Effect

The scientific method is used to determine whether a hypothesis—such as whether a relationship’s breaking up can lead to depression—has merit. The process of research on psychopathology often begins with observations that lead to a hypothesis about either the factors that may contribute to psychological disorders or the aspects of treatment that may be particularly helpful.

Scientists often collect quantitative data (numerical measurements, such as how many symptoms someone has, the number of weeks symptoms have been present, or how many people in the family have similar symptoms).

Scientific method

The process of gathering and interpreting facts that can lead to the formulation of a new theory or the validation or refutation of an existing theory.

Data

Methodical observations, which include numerical measurements of phenomena.

depression and breakups occur completely independently of each other. Many of the depressed students coming to the counseling center have had prior bouts of depression. In such cases, a breakup would not necessarily be the culprit, because those individuals might have had another bout of depression regardless. Alternatively, there may be a causal connection between breaking up and depression—but it could go either way, with either one leading to the other.

To determine whether your idea that the breaking up of a relationship can lead to depression is correct, you would use the **scientific method**, which is the process of gathering and interpreting facts that can lead to the formulation of a new theory or the validation or refutation of an existing theory. The steps of the scientific method normally are: observing relevant phenomena; identifying a question to be answered; developing a hypothesis that might answer the question; collecting new observations to test the hypothesis; drawing on the evidence to formulate a theory; and testing the theory.

The Scientific Method

Suppose that your casual observation is correct: Students who seek help for depression *are* more likely to have had a relationship breakup before the depression began. Knowing this, you are interested in understanding why some people get clinically depressed after a breakup (like Carlos), whereas other people bounce back. You may even have a hunch about why. But the scientific method of investigation relies on more than one individual’s impressions and hunches. How can the scientific method help researchers learn more about the association between breakups in relationships and depression or, more generally, about how a psychological disorder such as depression arises?

Collect Initial Observations

The first step in the scientific method is observation. Sometimes the initial observations lead immediately to the next steps, but other times they lead the researcher to describe the phenomenon more carefully and systematically by collecting data. **Data** are methodical observations, which include numerical measurements of phenomena. Scientific facts are based on such data. Data about depression and breakups, for instance, might include responses to a questionnaire on which people who have recently gone through a breakup rate their moods and functioning.

In most scientific fields, properly collected data can be **replicated** under identical or nearly identical conditions: Any other researcher, using the same collection method, should obtain a second set of data with the same characteristics as the first. For example, if a researcher at another college’s counseling center gave the same questionnaire about mood and functioning to a different group of students who’d recently suffered a breakup, that researcher would be trying to replicate the data.

Researchers collect data about *variables*: measurable characteristics of the object or event of interest. In the field of abnormal psychology, variables include activity in particular brain areas, hormone levels, the number of symptoms reported, the variety of abnormal behaviors exhibited, and types of observed interactions among family members. The list of variables of interest to researchers in psychopathology is long, as you will discover in this book. Variables can be *categorical* (for instance, someone either has or doesn’t have an older sibling) or on a *continuum* (for instance, someone can have a phobia that can be characterized from mild to severe).

Identify a Question

The process of explaining a set of observations begins by asking a specific question. Let’s say that your observations have led you to ask this question: “Why do some people get depressed after a relationship ends, rather than bounce back?” The question identifies an area where properly conducted research can point toward an answer.

Develop a Hypothesis

After identifying a question, a researcher then forms a *hypothesis*, which may or may not be the same as the original impression or hunch. A **hypothesis** is a preliminary idea that is proposed to answer the question about a set of observations. Hypotheses are important in part because they direct the researcher to make specific additional observations (which may include making precise measurements). The most common kinds of hypotheses propose a way to understand differences in measurements of a variable in different circumstances or to establish a relationship between variables. To develop a hypothesis, you need to propose some specific relationship for the variables in the question you've asked. For instance, a hypothesis might address *which people* are likely to get depressed or *why* some people are likely to get depressed. Let's say you develop this hypothesis: Individuals who suffered a major loss during childhood (such as the death of a parent) are more likely to get depressed after a relationship ends during adulthood. Your hypothesis involves two variables: one categorical (people either experienced a loss in childhood, or they didn't) and one continuous (depression can have different degrees of severity).

Collect Data to Test the Hypothesis

The next step involves systematically collecting data to test the hypothesis. For example, to test your hypothesis, you might recruit people who have just broken up with their spouse or partner. You might ask them to complete two questionnaires: one about any major losses they experienced in childhood, and the other about their current mood and functioning. Sometimes researchers compare two or more hypotheses, trying to determine which one best fits the data.

Develop a Theory

After enough data are collected and examined, the researcher proposes a **theory**, which is a principle or set of principles that explains a set of data. A theory provides an answer to the question identified by the researcher. For example, you might theorize that depression is particularly likely to arise in adults after a relationship breaks up if they, as children, suffered a loss and there was nothing they could do to control or manage the situation. In fact, as we saw in Chapter 2, when animals cannot control an aversive stimulus (a shock), they learn to become helpless; rather than try to escape from such a stimulus, they appear to give up. Such a process could underlie some forms of depression (Miller & Seligman, 1973, 1975). That is, according to this theory, the child forms an enduring association between loss and a sense of helplessness, and it is the feelings of helplessness that produce depression. Later in life, when the adult experiences a loss, this triggers the associations to helplessness, which in turn leads the adult to become depressed. This theory may apply to Carlos's case: His mother died of breast cancer when he was 6 years old, and he remembers feeling helpless during her illness and at her death.

Test the Theory

The next step of the scientific method is to test the theory by collecting and examining additional data. Your theory focuses on people who not only had a significant loss during childhood, but also felt helpless to control or manage the situation. The theory leads to **predictions**, hypotheses that should be confirmed if a theory is correct. So, for instance, the theory predicts that children who felt particularly helpless after a loss would be more likely as adults to become depressed after a relationship breaks up. Data can then be collected to address this specific prediction: In addition to questionnaires about early loss and mood and functioning, an additional questionnaire might ask about memories of feeling helpless. You could then test people who did or did not have an uncontrollable loss during childhood by giving them increasingly difficult puzzles; as a measure of helplessness, you would assess how easily participants give up trying to solve the puzzles. Figure 5.1 provides a summary of the steps of the scientific method.

Many methods can be used to test the predictions made by a theory, and we'll see what these are in the following section.

Replication

The process of repeating a study using the same data collection methods under identical or nearly identical conditions to obtain data that should have the same characteristics as those from the original study.

Hypothesis

A preliminary idea that is proposed to answer a question about a set of observations.

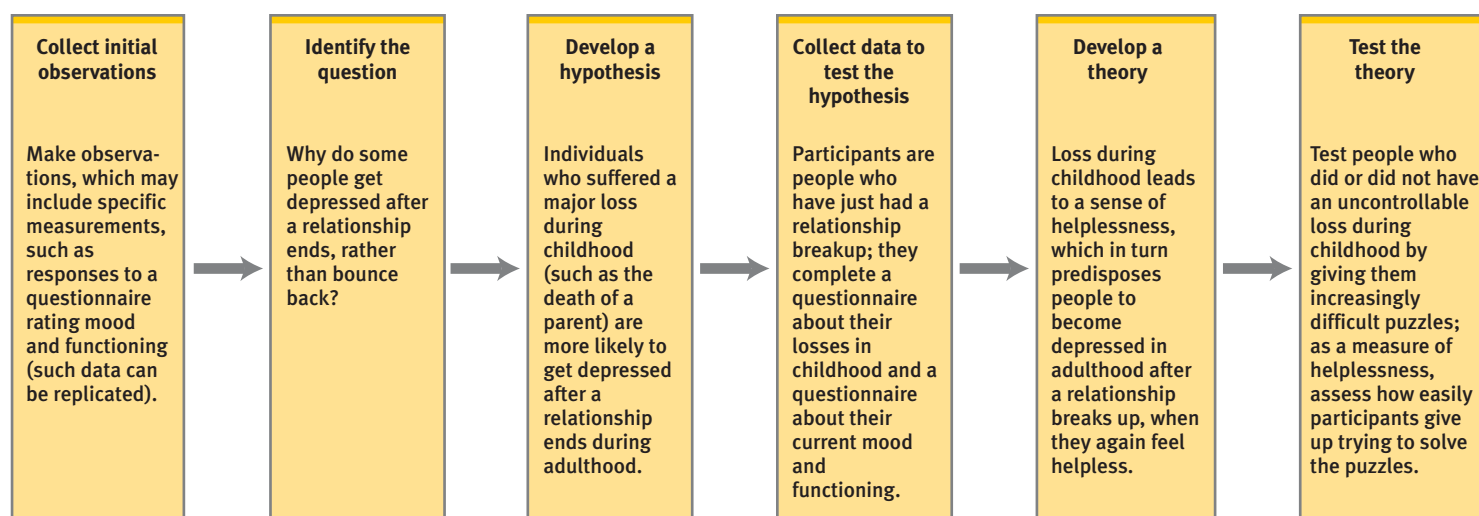

Theory

A principle or set of principles that explains a set of data.

Predictions

Hypotheses that should be confirmed if a theory is correct.

Figure 5.1

5.1 Steps of the Scientific Method

Types of Scientific Research

Any individual researcher does not need to go through the entire sequence to be doing science. For instance, you went from having an observation to identifying a question—about relationship breakups and depression—to stating a full-fledged theory: Children who felt helpless in response to a loss grow up to be especially susceptible to becoming depressed after a relationship fails. However, your observation could have led you down many other research paths, depending on the specific question you developed. For instance, your question might have focused not on loss during childhood, but on the degree to which the adult was not totally surprised by the breakup of the relationship.

Psychologists employ different research methods when they pose and attempt to answer various questions; such methods include experiments, quasi-experiments, correlational research, case studies, and meta-analysis. As we review the various research methods, we will point out not only their strengths, but also their weaknesses. You might be tempted to conclude that the weaknesses are so severe that you can never understand anything with certainty from psychological research. Resist that temptation! Although each method has limitations, different methods have different limitations. Thus, if different methods produce the same answer to a question, we can be confident that the limitations of any one method are not responsible for the results. This method of *converging evidence*, where the same answer is produced using different techniques, has produced a wealth of knowledge about psychopathology.

Conducting Research with Experiments

Ideally, researchers prefer to employ **experiments**, which are research studies in which investigators intentionally manipulate one variable at a time, and measure the consequences of such manipulation on one or more other variables.

Independent Variables and Dependent Variables

You probably noticed that the definition of an experiment mentioned two kinds of variables: those that are manipulated and those that then are measured. In an experiment, researchers manipulate one variable at a time in order to observe possible changes in another variable. The variable that a researcher manipulates is called the **independent variable** (so named because it is free to change—it is independent). The variable that may change as a result is called the **dependent variable** (because its value *depends* on the independent variable). When the independent variable is changed, the accompanying changes in the dependent variable are the *effect*.

Experiments

Research studies in which investigators intentionally manipulate one variable at a time, and measure the consequences of such manipulation on one or more other variables.

Independent variable

A variable that a researcher manipulates.

Dependent variable

A variable that is measured and that may change its values as a result of manipulating the independent variable.

A researcher might separately manipulate several independent variables (always keeping all else constant while a single variable is changed), hoping to discover which ones cause the greatest effect on the dependent variable.

Of course, researchers could not use an experimental design to investigate the specific question about helplessness during early loss and subsequent depression after a breakup. A researcher ethically cannot cause a person to have a major loss during childhood (or to feel helpless at the time). Participants in an experimental study come as they are—with particular neurological, psychological, and social histories that can't be changed.

This is why most of the research on causes of psychological disorders does not use an experimental design. For ethical reasons as well as practical ones, researchers cannot alter participants' genes, subject participants to high levels of stress, cause traumatic experiences to occur in their lives, or create disruptive family events—all of which would involve intentionally manipulating independent variables. However, some aspects of psychopathology can be studied with an experimental design. For instance, an experimental design has been used to study learned helplessness in dogs (see Chapter 2; Overmier & Seligman, 1967); the independent variable was whether the dogs could escape an electrical shock, and the dependent variable was the number of attempts to escape.

Similarly, Watson and Rayner's experiment with Little Albert (1920; see Chapter 2), used an experimental design to test a theory about the etiology of a phobia. In that study, the independent variable was whether or not the conditioned (that is, the initially neutral) stimulus had been paired with an aversive unconditioned stimulus. The dependent variable was the presence of fear-related behaviors—as measured by Albert's crying and trying to get away from the white rat. When the conditioned stimulus (CS) and the unconditioned stimulus (UCS) had not yet been paired, Albert was not afraid of the rodent. His fear-related behaviors (the dependent variable) depended on his exposure to the pairing of CS and UCS.

Other examples of experimental designs in research on psychopathology include studies of people who have *panic attacks*—specific periods of intense dread or fear, accompanied by physical symptoms of fear; the independent variable is the situation or condition that may induce a panic attack, and the dependent variable is the number of such attacks. Further examples include studies of people who have substance abuse problems, where the independent variable is the type of *cues*, or stimuli, that trigger cravings to take the drug or to drink alcohol, and the dependent variable may be intensity of cravings for the drug or alcohol or physiological measures of arousal.

You could use an experimental design to conduct research that relates to the relationship between childhood loss and mood. You might, for instance, select three groups of participants: those who had a childhood loss but were able to cope with it, those who had a loss and experienced helplessness (like Carlos), and those who did not have a loss (note that you are not manipulating this variable, and thus composing the three groups is not part of the experiment itself). You could then have the independent variable be the type of movie viewed by participants; the film could involve either the theme of loss or some other theme that does not involve loss. The dependent variable might be participants' ratings of mood after viewing the movie. Your hypothesis for this study might be that participants who had suffered a loss and experienced helplessness during childhood would have the most negative mood after watching a movie with the theme of loss.

If changes in the independent variable do in fact change the measurements of the dependent variable (that is, they produce an effect), there is a *relation* between the variables. But if the experiment has not been carefully designed this relation could be more apparent than real. Factors that might inadvertently affect the variables of interest in the experiment are called **confounding variables**, or **confounds**. For example, suppose that you conducted an experiment in which the independent variable was the type of movie viewed by participants, with one movie involving the death of a loved one and the other not touching on the theme of loss. Then suppose that the movie involving loss was always shown immediately after a serious drama for the “loss-helplessness” group, whereas the movie that did not involve loss was always shown immediately after

blickwinkel/Alamy

Some studies investigating psychopathology use an experimental design. Here the independent variable is different types of music and the dependent variable is depressed participants' self-reported mood after listening to the music.

Confounding variables (confounds)

Factors that might inadvertently affect the variables of interest in an experiment.

a comedy for the “loss-no helplessness” group. It could be the type of movie shown first—drama or comedy—and not differences between the groups that produces the effects on the dependent variable. Confounds lead to ambiguous or uncertain results. To minimize the possibility of confounds, the researcher should try to ensure that the experimental manipulation alters only the independent variables (and does not inadvertently affect other variables, such as the order in which the movies are presented) and that only those changes in the independent variables affect the dependent variable. It is not always possible to ensure that this is the case, however, and thus the experimenter must examine every reasonable hypothesis that might explain the effect.

Control Groups and Conditions

A common method for examining the possible effects of confounds in an experiment is to create a control group. The experimental group (or groups) and the control group are treated identically throughout the experiment, except that the independent variable is not manipulated for the **control group**. For example, say that your hypothesis was confirmed; the group of participants who had suffered an early loss and experienced helplessness did in fact have a more negative mood after watching a movie with the theme of loss. But here’s a potential confound: Maybe these people are just very sensitive to depressing movies in general, not to themes of loss specifically. To rule out this possibility, you would control for this factor by testing another group of these people, showing them a depressing movie that has nothing to do with loss. (This movie should be as similar as possible to the first one in every way, except that it does not have the theme of loss.) If your hypothesis is correct, then you should find a much larger drop in mood following the movie about loss than following the movie that was merely depressing—which would provide evidence that it’s the theme of loss itself that is important.

To use a control group appropriately, it must be as similar as possible to the experimental group. If the members of a control group differ significantly from members of the experimental group in terms of age, education, cultural background, temperament, or any other characteristic, one or more confounding variables has been introduced. Such a confound would cloud the interpretation of the results, because a difference in the dependent variable could be attributed to the confound instead of to the relation you intended to test. Perhaps the control group responded less strongly to the depressing movie simply because most of the participants in that group happened to be temperamentally placid.

You can imagine how hard it can be to match a control group perfectly to an experimental group. This difficulty often leads researchers to match the experimental group to the most similar possible control group: the experimental group itself! Sometimes, rather than having two separate groups that are treated differently, researchers have all participants take part in different *conditions*, or circumstances, which correspond to the different ways that experimental and control groups would be treated in a study that had both types of groups. For example, the same people could watch a movie about loss and at a different time watch a movie that was depressing but not about loss. However, when the same group of people take part in more than one condition, you need to avoid a confounding that might be introduced by the order of presentation of the conditions. For instance, if the “loss” film was always presented first, it could be that the participants were more alert during that part of the study, and that’s why they responded differently. To avoid this, you would *counterbalance* the order of exposure to each condition: Half of the participants would watch the “loss” film first, and the other half would watch the “non-loss/depressing” film first. This procedure would ensure that each condition occurred equally often in each place in the order of presentation.

Control group

A group of participants in an experiment for which the independent variable is not manipulated, but which is otherwise treated identically to the experimental group.

Bias

A tendency that distorts data.

Bias

The way a study is set up can affect the assignment of participants into groups or influence the outcome of the experiment. For instance, suppose that you have two groups: members of one group see a “loss” film and members of the other see a “non-loss/depressing” film. When you assign participants to the groups, you

inadvertently assign the people who smile at you to the “non-loss” group. Whether or not it is conscious (intentional) or unconscious (unintentional), a tendency or influence that distorts data—which ends up producing a confound—is called **bias**. This is why researchers place participants in groups using **random assignment**, assigning participants to each group by a procedure that relies on chance.

Even if you randomly assign participants to groups or have them take part in both conditions, other biases can interfere. Perhaps all your participants come from the same city, which recently experienced a devastating hurricane (and so the theme of loss is particularly salient for all participants). **Sampling bias** occurs when the participants are not drawn randomly from the relevant population. Sampling bias needs to be avoided if you want to be able to *generalize* (i.e., extrapolate) from the people in your study to the population at large. This brings us to an important distinction: The **population** is the complete set of possible participants (e.g., all rats or all people, or in certain cases all people of a particular age, gender, or race). The **sample** is the small portion of the population that is examined in a study.

Many of the same points also apply to the items that are selected to be used as stimuli in the study. For example, you might select a very powerful “loss” film and a limp “depressing” film—or vice versa. In this case, an irrelevant characteristic of the items—how powerful they are—might determine the results. Just as you need to be careful in sampling and assigning participants to groups, you need to be careful in selecting the items (such as the specific items in a questionnaire), ensuring that they are in fact representative of the types of items to which you want to generalize.

Internal and External Validity

A study has **internal validity** if it controls for possible confounding variables. Internal validity means that variations in the independent variable are in fact responsible for variations in the dependent variable (or variables, in studies in which more than one type of measurement is taken) and that the results are not a by-product of other, extraneous variables.

A study is said to have **external validity** when the results generalize from the sample (the particular participants who were tested) to the population from which it was drawn and from the conditions used in the study (such the particular movies shown, in the example study) to similar conditions outside the study. If a study does not have internal validity, it cannot have external validity. In contrast, even if a study has internal validity (its results have not been confounded), this does not guarantee that it will have external validity (that its results apply to relevant situations or other people).

Quasi-Experimental Design

Ideally, the participants in a study are randomly assigned to groups. But, in many cases, random assignment is not ethical, desirable, or possible. For instance, when trying to test hypotheses about why a disorder develops, researchers cannot “assign” one group to have a particular set of genes or brain functioning, a particular way of thinking, a particular type of traumatic experience, or particular friends or families. Therefore, in trying to understand possible causes of psychopathology, researchers often use *quasi-experimental designs*, which rely on groups that already exist. In fact, the “experiment” that we have been discussing is—like much research on psychopathology—a blend of experiment (manipulation of independent variable and measurement of dependent variable) and quasi-experiment (the selection of participants from pre-existing groups).

Corbis/Punchstock

Suppose you want to know what the prevalence is in the United States of the type of depression that results from seasonal changes in the amount of daylight (sometimes referred to as *seasonal affective disorder*). You are a researcher in Portland, Oregon, and are collaborating on the study with researchers in Boston, New York, Chicago, and Detroit. Participants in the study are drawn from those five cities. Do you see the sampling bias problem? All these cities are in the northern half of the United States and therefore have a different number of daylight hours than does the southern half. Whatever prevalence rate was calculated would not reflect the entire United States.

Random assignment

Assigning participants to each group in a study using a procedure that relies on chance.

Sampling bias

The distortion that occurs when the participants in an experiment have not been drawn randomly from the relevant population under investigation.

Population

The complete set of possible relevant participants.

Sample

The small portion of a population that is examined in a study.

Internal validity

A characteristic of a study, indicating that it measures what it purports to measure because it has controlled for confounds.

External validity

A characteristic of a study, indicating that the results generalize from the sample to the population from which it was drawn and from the conditions used in the study to relevant conditions outside the study.

Correlation

The relationship between the measurements made of two variables in which a change in the value of one variable is associated with a change in the value of the other variable.

Correlation coefficient

A number that quantifies the strength of the correlation between two variables; the correlation coefficient is most typically symbolized by r .

Statistically significant

The condition in which the probability of obtaining the value of a statistical test is greater than what would be expected by chance alone.

A correlational study found that suicide is more likely to be the cause of death in high-altitude states, such as Colorado, than in lower altitude states (Cheng, 2002). This relationship may arise for any number of reasons, such as decreased levels of oxygen from the higher altitude (McCook, 2002), the challenges of mountain living, differences in the age and education levels of the populations, or perhaps the fact that depressed people seek a type of solitude more often found in high-altitude states. One possible confound the study did not control for was the amount of time those who committed suicide had lived at the higher altitude: Those who were born in high-altitude states would have adapted to the lower oxygen level. Researchers could have investigated one possible explanation by examining this variable (McCook, 2002).

Paul Chesley/Getty Images

To be a true experiment, you would need to have assigned participants randomly to the three groups (loss with helplessness, loss without helplessness, and no loss) *during childhood*. Obviously, this is undesirable and impossible. But in a quasi-experimental design, you can sort participants into groups—those who had a childhood loss and experienced helplessness, those who had a childhood loss but didn't experience helplessness, and those without a childhood loss. Then you would show people in all three groups a film that involves relationships breaking up. After viewing the film, participants in all three groups would rate their mood. Your hypothesis is that participants who experienced early loss and helplessness (like Carlos) will report greater sadness after seeing the film than will those in the other two groups. With a quasi-experimental design, you still try to control as many variables—such as age, health, education, and economic level—as you can in order to make the groups as similar as possible.

Correlational Research

Experiments and quasi-experiments allow researchers to zero in on which variables cause which effects. In some cases, however, manipulating the variables, even in a quasi-experiment, can be unethical or difficult. This is an issue for any study that involves participants' histories—such as medical histories, family histories, or experiences they had when younger. When independent variables can't or shouldn't be manipulated, researchers can study the relations among variables by looking for a **correlation**, a relationship between the measurements made of two variables in which a change in the value of one variable is associated with a change in the value of the other variable. A correlation compares two measurements and records the amount of similarity in their variations; the stronger the correlation, the more closely related the variables are. There are no independent and dependent variables in *correlational research*: Nothing is manipulated; instead, naturally occurring variations among measurements of different variables are compared. These comparisons can involve measures from different individuals or groups or measures from the same participants at different times. For example, if your study were correlational, your two variables of interest might be the extent to which a child experienced helplessness during a loss (perhaps rated by relatives who were present at the time or by the person's memory of how severe the sense of feeling helpless was) and the number of symptoms of depression experienced as an adult, after a breakup. Twin studies (discussed in Chapter 2) often involve correlational research.

Correlation Does Not Imply Causation

A major disadvantage of correlational methods is that they only indicate that two variables are related. A correlation does not demonstrate that either variable *causes* the other to change. In an experiment or in a quasi-experiment, the point is to show

that changes in the independent variable *cause* changes in the dependent variable. In contrast, a correlational research study can only show that the values of two variables are related. For example, although the degree of helplessness felt during childhood loss and the amount of depression after an adult relationship breaks up may be correlated, the loss experienced after the breakup may not be the cause of the depression. As discussed earlier, it could be that depression comes first, and it causes the breakup! Simple correlations do not control for possible confounding variables. Perhaps experiencing helplessness as a result of an early loss leads people to be passive, and that in turn leads them to have fewer friends or family members who are supportive. It may be the relatively low amount of support received after a relationship breaks up that makes people vulnerable to depression. Such a factor could have contributed to Carlos's depression after his relationship with Liana ended.

Professors who teach statistics are fond of having their students memorize a simple statement: *Correlation does not imply causation*. To determine causation, a researcher must manipulate an independent variable while holding everything else constant. Only then can the results demonstrate that changes in the independent variable actually caused changes in the dependent variable.

Measuring a Correlation

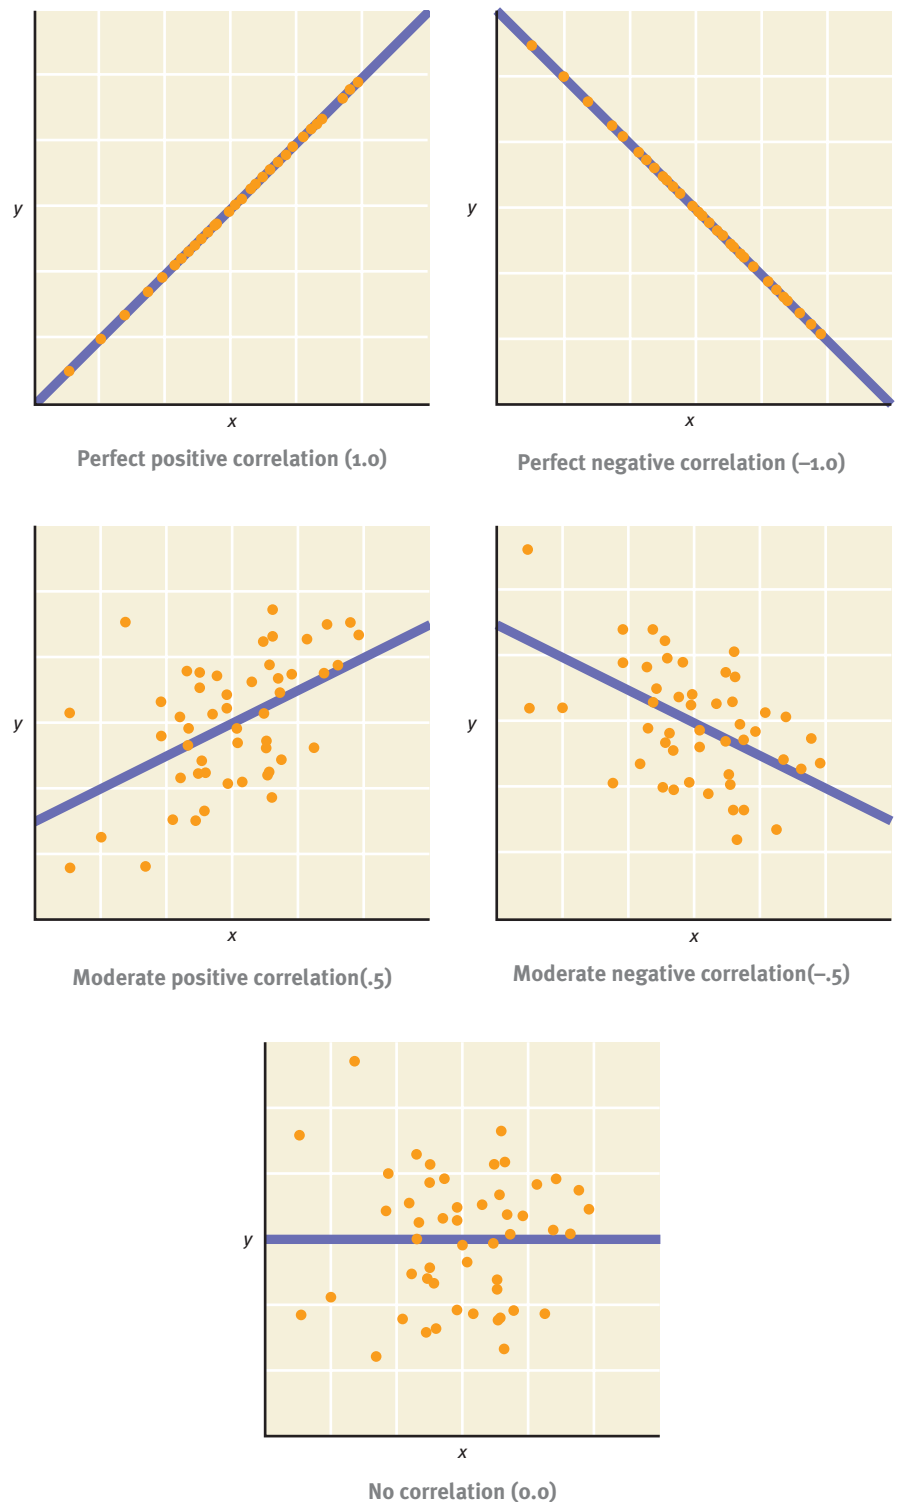

The strength of the correlation between any two variables is quantified by a number called a **correlation coefficient** (most typically symbolized by r). When this number is positive, it signifies that the variables change in the same direction; both variables either increase or decrease in the same general pattern. A *positive relationship* is indicated by any correlation coefficient between 0 and +1. When the correlation coefficient is negative, it signifies that the variables change in opposite directions in the same general pattern; one goes up while the other goes down. A *negative relationship* is indicated by a correlation coefficient between 0 and -1. In either case, positive or negative, the stronger the relationship, the closer the coefficient is to +1 or -1. If the variables do not have any relationship at all, the correlation coefficient is 0.

If you plot two variables on a graph, putting one variable on each axis, you can see whether or not the variables change together. The closer the data points are to a straight line, the stronger the correlation. Figure 5.2 illustrates five possible correlations. When you draw a line through the data points as in the figure, you can measure the distance (parallel to the vertical axis) between each point and the line. The shorter these distances, on average, the stronger the correlation (leaning toward +1 or -1). Computer programs that perform statistical tests use a mathematical formula to calculate the correlation coefficient.

Statistical Significance

Even when variables are completely independent, they might vary in the same pattern simply by chance. In fact, the correlation coefficient between any two randomly selected sets of data is very seldom exactly 0. A correlation coefficient is **statistically significant** when it is greater than what would be expected by chance alone. Statistical significance is not the same thing as “importance.” It simply means that the observed result is unlikely to be a quirk of random variation in the data. Suppose, for your participants, you calculated the correlation between age when experiencing a loss during childhood and symptoms of depression after an adult breakup, and the result was $r = -0.11$. This means the younger

Figure 5.2

5.2 ▶ Five Values of Correlation

Epidemiology

The type of correlational research that investigates the rate of occurrence, the possible causes and risk factors, and the course of diseases or disorders.

Longitudinal studies (in studies of psychopathology)

Research studies that are designed to determine whether a given variable is a risk factor by using data collected from the same participants at various points in time.

Results of epidemiological research indicate that people who engage in pathological gambling—their gambling is compulsive—are at high risk to have an alcohol or drug problem (Petry, Stinson, & Grant, 2005). However, finding such a correlation does not tell us *why* there is a relationship between gambling and substance use problems.

Getty Images

a person was when a loss occurred, the more symptoms of depression he or she is likely to have after a breakup as an adult. However, this relationship may not hold for every participant.

You could determine whether the correlation coefficient is statistically significant through a calculation that depends partly on the number of data points you have. All else being equal, the more data points, the smaller the correlation coefficient needs to be to count as statistically significant. Why is this so? Consider the finding for gifted children of negative correlations between measures of self-esteem and depression and also between measures of self-esteem and aggression (in other words, gifted children who had lower self-esteem also tended to be depressed and to be more aggressive; Benony et al., 2007). If this study had involved only 4 gifted children (instead of the 23 actually examined), the correlations could easily reflect the luck of the draw: Perhaps the day before the study one of the 4 children had misread the instructions for an important test, which he then failed dramatically. That experience might have produced temporary low self-esteem and also made him feel depressed and aggressive. A chance event would have made the sample for this study nonrandom. Alternatively, suppose that one of the 4 children had absolutely aced an important test at school the day before—and so was feeling especially good about herself and not depressed or aggressive. This too could distort the results. In contrast, if the study had 100 children as participants, the chances that some would have had an experience that produced temporary low self-esteem would likely be balanced by the chances that some would have had an experience that produced the opposite effect. The bottom line: The larger the sample, the more likely that random variations going in one direction will be canceled out by random variations going in the other direction. Thus, the larger the sample, the smaller the correlation coefficient needs to be for you to be confident that the observed relationship is not a result of chance.

Researchers want to know not only the correlation coefficient, but also the value of p (which stands for *probability*) that is associated with that coefficient; the value of p indicates how likely it is that the correlation could have arisen due to chance. In the study just mentioned, the correlation between a measure of self-esteem and a measure of depression was $r = -.59$, and this coefficient was tied to $p < .01$. This means that the probability that the correlation is due to chance is less than 1 in 100. Similarly, a value of $p < .05$ means that the probability that the correlation is due to chance is less than 5 in 100. In fact, $p < .05$ is usually considered the cutoff for statistical significance. You can check the significance of the value of p for a data set by consulting a published table (which appears in appendixes of most statistics textbooks). Computer software that calculates the correlation coefficient usually gives the value of p as well.

Using Correlational Methods

Much of the research on defining and understanding psychopathology is correlational. That is, it is designed to discover whether one variable (a disorder or a symptom) is linked to other variables (such as alterations in neural activity, irrational thoughts, or family functioning). **Epidemiology** is a type of correlational research that investigates the rate of occurrence, the possible causes and risk factors, and the course of diseases or disorders. Thus, in epidemiological studies of psychopathology, researchers identify people with one (or more) disorder and correlate the presence or severity of the disorder with other variables, such as the age of onset of the disorder, the number of people in the family who have had symptoms of the disorder, or socioeconomic status.

Note that certain factors (such as having a relative with a disorder) can be *risk factors*, which increase the likelihood of developing a disorder. However, by definition, risk factors are simply that—risks, not destiny. How are such risks identified? Studies often use correlational data to determine whether people who have a psychological disorder are different in some way from people who don't have the disorder. Some of these studies are **longitudinal studies**, which are designed to determine whether a given variable is a risk factor by

using data collected from the same participants at multiple points in time. Specifically, such studies track a group of children or adults over time and observe whether a disorder develops. The presence or absence of the disorder is then correlated with a neurological factor (perhaps information about brain structure or function or hormone levels), a psychological factor (cognitive or emotional functioning, beliefs, or personality traits), or a social factor (family and other intimate relations, school performance, or socioeconomic status) that typically was assessed at an earlier point in time. Factors that are significantly correlated with the subsequent emergence of the disorder are taken to signal risk for developing that disorder. However, because such longitudinal studies are usually correlational, researchers cannot infer causality on the basis of the findings. As with virtually all correlational studies, many factors can explain differences observed in longitudinal studies.

Case Studies

Research on psychopathology may also rely on **case studies**, which focus in detail on one individual and the factors that underlie that person's psychological disorder or disorders. For instance, someone noticed that a patient had a very bad sore throat prior to developing symptoms of *obsessive-compulsive disorder* (OCD)—a disorder that is characterized by frequent and intrusive unwanted thoughts and behaviors that the individual feels compelled to engage in (we will say more about this in Chapter 7). Studies that were inspired by this observation found that OCD may sometimes develop from a particular type of streptococcal infection (Swedo et al., 1998), and eventually researchers identified *pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection* (PANDAS; Giulino et al., 2002). PANDAS appears to arise, at least in part, when antibodies that attack the strep bacteria also attack the brain's basal ganglia. Antibiotics that treat the strep infection (leading to lower levels of antibodies) end up decreasing the OCD symptoms. The discovery of PANDAS began from a case study. However, additional crucial information could only be revealed by group studies. For example, parents and siblings of those who develop PANDAS-related OCD have a higher rate of OCD than does the general population (Lougee et al., 2000), which suggests that a person's neurological vulnerability affects whether he or she will develop the disorder when infected by this type of strep.

Case studies can alert clinicians to possible factors that may exacerbate symptoms of a particular disorder. Case 5.1 is about such a problem affecting a young woman with *autism*—a disorder that is diagnosed in childhood and involves significant problems with communication and social interactions (we'll discuss this disorder in more detail in Chapter 14).

CASE 5.1 ► FROM THE OUTSIDE: Menstruation-Related Exacerbation of Autism Symptoms

A 19-year-old nonverbal girl fulfilling *DSM-IV* criteria for autism and severe mental retardation was referred for aggression and SIB [self-injurious behavior]. At onset of menarche at age 12, agitation dramatically increased. Her mother recorded cyclical behavioral changes along with her menses. Before each menses, she became withdrawn, apathetic, quiet, irritable, and easily agitated with increased tantrums and appeared anxious. She also had a cyclical amplification of baseline autistic behaviors: stereotypies (rocking), sensitivity to changes, and sensitivity to noise. New-onset cyclical hand-biting was so intense that scarring resulted, and cyclical aggression directed at objects and others occurred several times daily. Teacher reports recorded and corroborated aggression and SIB that corresponded to the days before the onset of her menstrual period. Within 1 day of menstrual onset, mood symptoms and SIB abated. Neither behavioral therapy with positive or negative reinforcement nor treatment with acetaminophen or ibuprofen yielded improvement. Treatment with paroxetine [Paxil, an SSRI medication] 20 mg every morning resulted in improvement of premenstrual mood symptoms and premenstrual exacerbated SIB. On discontinuation of paroxetine on two distinct occasions, cyclical mood symptoms, aggression, and SIB returned.

(Lee, 2004, p. 1193)

AP Photo/Peter Dejong, Pool

Risk factors are usually variables that are associated—correlated—with the later emergence of psychological disorders. For instance, soldiers who fought in the Gulf War in 1991 were more likely to develop psychological disorders in the next year than were soldiers deployed elsewhere during that time period (Fiedler et al., 2006). However, the presence of risk factors doesn't guarantee that a disorder will develop.

Case studies (in studies of psychopathology)

A research method that focuses in detail on one individual and the factors that underlie that person's psychological disorder or disorders.

Uses and Limits of Case Studies

A case study focuses on a particular individual in detail, often describing neurological, psychological, and social factors: Such a study often provides information about a person's medical and family history, as well as his or her culture and the context of the problem. Mental health professionals use case studies for a variety of reasons:

- to demonstrate some aspect of diagnosis, etiology, or treatment;
- to provide support for (or evidence against) a particular hypothesis or theory; and
- to train other mental health professionals, who are given case studies and must then propose diagnoses and appropriate treatments.

This book includes numerous case studies so that you can gain a sense of how psychological disorders affect people's lives. Case studies with *From the Outside* in the title describe an individual with a disorder from a mental health professional's point of view. Case studies with *From the Inside* in the title are first-person accounts, allowing you to get a patient's point of view on what it is like to have a disorder or particular symptoms of a disorder.

Mental health clinicians and researchers must resist the temptation to generalize from a single case: Don't assume that the findings from a case study necessarily can be extended to other similar cases, let alone to the population at large. Sometimes the findings can be generalized, but sometimes they cannot be; every individual is unique, and a person's particular history presents many possible confounding factors. In addition, if a case study relies on correlations among variables, this method—as usual—prevents us from drawing conclusions about causality.

Single-Participant Experiments

Case studies are not necessarily limited to describing the values of variables and relations among them. In some situations, clinicians and researchers can actually perform experiments with only a single case. For instance, a researcher could treat someone suspected of having PANDAS-related OCD with antibiotics and determine whether the OCD symptoms improved. Experiments with only a single case are called **single-participant experiments**. Watson and Rayner conducted a single-participant experiment with Little Albert.

Single-participant experiments may rely on an *ABAB design*, which is often used to measure change in target behaviors as the result of some treatment. In many cases, the baseline condition is the first A, and administration of a treatment (e.g., behavior modification, or any other type of treatment) is B. A single participant receives both conditions: a baseline condition with no treatment (the first phase A of the ABAB design), and the treatment (phase B of the ABAB design) (Drotar, 2006). The data for the target behavior in the baseline phase (A) are compared to the data for that behavior in the next phase (B).

In the second A phase, the treatment in phase B is withdrawn, and researchers can determine whether, or how quickly, the person's targeted behavior returns to baseline (for example, withdrawing behavior modification treatment and observing what happens with extinction). This second A phase addresses the question "Will any behavior change from the previous phase persist once treatment is withdrawn?" The treatment is then presented again in the second B phase.

For instance, people with autism (such as the young woman in Case 5.1) have difficulty taking another person's perspective. One method to help them with this social skill is to tell them stories in which who, what, when, where, and why are clear—and ample information is given about the different characters' perspectives (Gray, 1996). Such stories are read aloud to the patient from a picture book. Results of previous research with social stories indicate that they can be helpful, but in most of those studies the stories were part of a comprehensive intervention that included other treatments such as social skills training (Swaggart et al., 1995).

A single-participant experiment was performed to determine whether social stories alone could help decrease tantrums in a 5-year-old boy, Gregg, diagnosed

Single-participant experiments

Experiments with only a single participant.

with autism (Lorimer et al., 2002). Gregg's tantrums involved screaming, kicking, and throwing things and were thought to be efforts to obtain attention. Before a tantrum, Gregg would "rev up" by shouting commands for attention, such as "Listen to me!"; these commands were referred to in the study as "interrupting verbalizations." When his parents or therapist ignored these commands (trying to extinguish the behavior), Gregg went into a tantrum; the episodes of interrupting verbalizations and tantrums would last at least 45 minutes. These episodes occurred about five times each day, usually when his parents or other adults weren't paying attention to him or when he had to wait to play with a particular object.

Social stories about adults talking to other adults and about having to wait were read to Gregg:

- each morning,
- at the beginning of each therapy session,
- right before the adult with him was to withdraw attention from him to talk to someone else, and
- when he was about to be asked to wait.

Then, when his interrupting behaviors began, Gregg was asked to look at his social storybook and figure out what appropriate behaviors would be.

Researchers collected data on the frequency of Gregg's target behaviors. In Gregg's case, the treatment was the use of social stories, and there were two dependent variables: the frequency of interrupting verbalizations and the frequency of temper tantrums. In the A phase of the ABAB design, no stories were told; in the B phase, the stories were told. Figure 5.3 illustrates the results: The social stories were an effective means of reducing Gregg's interrupting verbalizations and tantrums. Note that once the stories were withdrawn (the second A phase), the target behaviors increased the subsequent day. Moreover, by the end of the second B phase, Gregg's interrupting verbalizations decreased even more than they did in the first B phase.

Single-participant experiments can help clinicians who want to know the extent to which an intervention

Figure 5.3

5.3 ▶ Results From a Single-Participant Experiment This single-participant experiment, using an ABAB design, shows the frequency of Gregg's interrupting verbalizations and tantrum behaviors over the course of the experiment.

can modify a patient's behavior. However, like case studies, single-participant experiments consider only one individual, so the results can be specific to that individual and based on neurological, psychological, or social factors that may not apply to others, or at least not in the same combination. Moreover, other confounding variables—such as the therapist's enthusiasm for the treatment, rather than the treatment itself—limit the generalizations that can be made. When the results of single-participant experiments are published, it is often with the goal of informing clinicians about possible interventions that might work for patients with the same problem and in similar circumstances.

Meta-Analysis

Despite the best efforts of researchers to minimize confounds, the results of any one study must be taken with a grain of salt—it's not clear whether researchers would obtain similar results if the study were undertaken in somewhat different circumstances. Perhaps the significant results found in one study were a fluke—or perhaps the lack of significant results in another study was a fluke. Such flukes can arise, in part, because of the particular people who were studied. Just as people vary in height and weight, they also vary in their behavioral tendencies, cognitive abilities, personality characteristics, and symptoms. This variety means that different samples from the same population can vary substantially, and when a sample is relatively small, chance variation can produce an appearance of a difference when such a difference doesn't really exist, or can obscure the measurement of an actual difference in the population. Moreover, sometimes an individual study does not produce a significant finding, but instead reports a near miss (for example, $p < .07$, which is above the critical .05 cutoff). If enough studies report similar near misses, there may be an effect, but it just isn't being measured well enough.

But how can researchers statistically evaluate more than one study that examines the same question? **Meta-analysis** is a research method that statistically combines the results of a number of studies that address the same question. This strategy can be especially valuable when some studies show an effect but others do not (Rosenthal, 1991). Because a meta-analysis increases the size of the overall data set, it can help to determine whether or not certain variables are related. In many cases, when studies are considered together in a single meta-analysis, the effect emerges loud and clear. A meta-analysis can uncover a relationship that is not apparent in any single study, which considers only a single sample from a particular population.

For instance, some clinicians have claimed that people with schizophrenia who have more insight about their disorder and its consequences also display fewer symptoms than do people with schizophrenia who have less insight. However, studies that address this claim have yielded inconsistent results: Some suggest a relationship between insight and number of symptoms, whereas others do not. Researchers conducted a meta-analysis of 40 studies on this relationship, and the results indicate that greater insight is in fact associated with fewer symptoms overall (Mintz, Dobson, & Romney, 2003).

However, meta-analyses have certain drawbacks. For one, there's the so-called *file drawer problem*. The results of studies that failed to find effects may linger in a researcher's file drawer, never making it to publication and thus never being included in a meta-analysis—and it can be difficult to estimate how many such negative findings there are. For another, not all studies are conducted equally well (e.g., some have more confounds than others). Some researchers have therefore asserted “garbage in, garbage out”: If the individual studies are no good, why should we believe that aggregating them is a good idea? Thus, although meta-analyses can reveal underlying regularities in results from different studies, they must be followed up with new studies that directly test their conclusions.

Table 5.1 provides a summary of the different research methods we've discussed.

Meta-analysis

A research method that statistically combines the results of a number of studies that address the same question to determine the overall effect.

Table 5.1 ▶ Research Methods in Psychopathology

Research Method	Important Feature(s)	Drawback(s)
Experimental Design	Use of independent and dependent variables and random assignment allows researchers to infer cause and effect.	Most research on etiological factors that contribute to psychopathology cannot be studied with experiments (but experiments are often used to study the effects of treatment).
Quasi-experiments	Used when it is possible to identify independent and dependent variables, but random assignment of participants to groups is not possible; researchers can still infer cause and effect.	Because random assignment isn't possible, possible confounds are difficult to eliminate.
Correlational Research	Used when it is not possible to manipulate independent variables such as etiological factors; researchers can examine relationships between variables.	Results indicate only <i>related</i> factors, not <i>causal</i> factors.
Case Studies	Often descriptive, but can use any of the research methods applied to a single participant.	Caution must be exercised in generalizing from the sole participant to others; there are many possible confounding factors.
Single-Participant Experiments	An experiment with one participant (and so random assignment isn't possible); cause and effect can be inferred.	Caution must be exercised in generalizing from the sole participant to others; there are many possible confounding factors.
Meta-analysis	A statistical analysis that combines the results of a number of studies that examine the same general question to determine the overall effect.	It is difficult to estimate the number of studies that failed to find an effect and thus were not published and not included in the analysis; the studies analyzed are often not of equal quality but their results are nevertheless weighted equally in the analysis.

Ethical Guidelines for Research

In theory, you could use an experimental design to test your hypothesis about childhood loss and adult depression after a breakup. This would involve long-term planning. First, you would have to find children who volunteer (and understand what they are volunteering for) to participate in the research project. Then, you would have to randomly assign each of them to one of three different groups: (1) a group that would suffer an early loss in the family—such as their parents' divorcing and a parent's moving far away—and also experience helplessness; (2) a group that would suffer an early loss in their family without feeling helplessness (for instance, the experimenter might allow the child to convince a parent not to move away); or (3) a group that would not suffer an early loss in their family. During their college years, you could, in theory, randomly assign some participants in each group to be dumped by a boyfriend or girlfriend.

Obviously, were there such a study, people would not be clamoring to participate. But what if people did volunteer for the study—should it be conducted? What if parents volunteered their young children? In such cases, it's easy to say, "of course not!" It would be morally and ethically wrong to inflict such loss and emotional turmoil for the sake of a research study. More generally, certain methods are obviously unethical. Everyone would agree that it would be wrong to traumatize people in order to learn why some develop chronic psychological problems afterward and some don't. Similarly, it would be unethical to cause people to become addicted to drugs in order to do research on how easily they can overcome the addiction.

But most ethical issues are not so clear-cut. How, then, do researchers decide which research studies are ethical and which are not? To address this question,

Table 5.2 ▶ Information Provided for Obtaining Informed Consent

When obtaining informed consent from participants, a researcher must give participants the following information:

- (1) the purpose of the research, expected duration, and procedures;
- (2) their right to decline to participate and to withdraw from the research once participation has begun;
- (3) the foreseeable consequences of declining or withdrawing;
- (4) reasonably foreseeable factors that may be expected to influence their willingness to participate such as potential risks, discomfort, or adverse effects;
- (5) any prospective research benefits;
- (6) limits of confidentiality;
- (7) incentives for participation; and
- (8) whom to contact for questions about the research and research participants' rights.

psychologists have developed ethical guidelines for research, which are part of the overall ethical code for psychologists. For instance, before someone participates in a study, the investigator must provide information describing the study, as outlined in Table 5.2. If a person decides to participate after reading the information, he or she signs an *informed consent* form. By signing, the person acknowledges that he or she understands what is involved in the study and agrees to participate, knowing that he or she can withdraw from the study at any point (American Psychological Association, 2002).

Another ethical guideline for research is that investigators must *debrief* participants after a study is over. They must ask each participant about his or her experience, particularly about any negative aspects of the experience (in part so that the study can be adjusted to minimize possible negative experiences for future participants). Investigators must also clear up any misconceptions that the participant may have about the study (American Psychological Association, 2002).

In addition, agencies that fund research on psychopathology and treatment require that the study be reviewed and approved by an institutional review board (IRB) in the setting that hosts the study (e.g., hospital, university, or clinic). The IRB is composed of scientists, clinicians, and members of the community at large. The board evaluates each study's possible risks and benefits, and then decides whether the study should be approved. This serves as another check on any ethical issues that might arise while a study is being conducted or afterward.

Key Concepts and Facts About Using the Scientific Method to Understand Abnormality

- Researchers use the scientific method to understand and study psychopathology. In doing so, they observe relevant phenomena, identify a question to be answered, develop a hypothesis that might answer the question, collect new observations to test the hypothesis, draw on the evidence to formulate a reasonable theory, and test the theory.
- When conducting experiments, researchers systematically manipulate one or more independent variables (changing one at a time) and observe possible changes in one or more dependent variables. Researchers examine the possible contribution of confounds by using control groups or control conditions. To minimize unintentional bias, they randomly assign participants to groups. In addition, stimulus items are chosen to assess the relevant variables, and confounding characteristics are eliminated. Experiments should have both internal and external validity.
- Researchers may use a quasi-experimental design when random assignment is not ethical, desirable, or possible.
- Correlational research is used when independent variables cannot or should not be manipulated. Such studies allow researchers to investigate the relationship between two variables, specifically, whether a change in one variable is associated with a change in the other. However, a correlation does not imply causation; it only indicates that the two variables are related. The strength of the relationship is quantified by the correlation coefficient, r , which can range from -1 to $+1$, with a higher absolute value indicating a stronger relationship. Statistical significance indicates that the obtained measurement is greater than would be expected by chance alone. Longitudinal studies of psychopathology often use correlational data.
- Case studies allow a clinician or researcher to examine one individual in detail. Single-participant experiments (often using an ABAB design) provide information about how one variable affects another. However, information from a particular case may not generalize to others.
- Meta-analysis allows researchers to aggregate the results of a number of related studies in order to determine the relations among certain variables.
- Psychologists have developed an ethical code of conduct that lays out guidelines for research, including the requirements that informed consent must be obtained from participants and that participants must be debriefed after a study is over.

Research Challenges in Understanding Abnormality

Let's examine your hypothesis about the relationship between experiencing a childhood loss and feeling depressed after a breakup in adulthood. How can we use the neuropsychosocial approach to understand why breaking up can lead some people to become depressed? We could investigate neurological mechanisms by which early loss, associated with helplessness, might make people more vulnerable to later depression, perhaps through enduring changes to brain structure or function. We could investigate psychological effects resulting from early loss, such as learned helplessness, cognitive distortions, or problems with emotional regulation. We could investigate social mechanisms, such as the way the loss altered subsequent attachments to and relationships with others or how economic hardships arising from the early loss created a higher baseline of daily stress. And, crucially, we could propose ways in which these possible factors might interact with one another. For example, perhaps daily financial stress not only increases the degree of worrying about money, but also such worrying in turn changes neurological functioning as well as social functioning (as preoccupying financial worries alter social interactions).

Whatever type of factors researchers investigate, each type comes with its own challenges, which affect the way a study is undertaken and which limit the conclusions that can be drawn from a study's results. Let's examine the major types of challenges to research on the nature and causes of abnormality from the neuropsychosocial perspective.

Challenges in Researching Neurological Factors

DSM-IV-TR does not consider neurological factors when assigning diagnoses, but many researchers are exploring the possible role of neurological factors in causing psychological disorders. This research is yielding new insights into why some of us, in some circumstances, develop psychological problems. In fact, current findings about neurological factors are coming to play an increasingly large role in treatment.

With the exception of genetics, almost all techniques that assess neurological factors identify abnormalities in the structure or function of the brain. This assessment is done directly (e.g., with neuroimaging) or indirectly (e.g., with neuropsychological testing or measurements of the level of stress hormones in the bloodstream). Such abnormalities are associated (correlated) with specific disorders or symptoms. For instance, people with schizophrenia have larger than normal ventricles (the fluid-containing cavities in the brain) and other areas of the brain are correspondingly smaller (Vita et al., 2006). Like all correlational studies, the studies that revealed the enlarged ventricles cannot establish causation. That is, these results cannot establish whether:

- schizophrenia arises because of the effects of this brain abnormality;
- episodes of psychosis somehow create larger ventricles (in essence, schizophrenia, over time, creates the brain abnormality);
- the brain abnormality existed before symptoms of schizophrenia developed; or
- the brain abnormality arises from some other factor, such as the effects of medications for schizophrenia. (We will revisit these possible causes in Chapter 12, when we discuss schizophrenia in more detail.)

Another limitation of research using neuroimaging is that we do not yet have a complete understanding of what different parts of the brain do. Thus, researchers cannot be sure about the implications of structural abnormalities (e.g., enlarged ventricles) or functional abnormalities (e.g., why specific areas that are normally activated during a task are not activated when a person with a particular disorder performs the task). For example, the parietal lobes are involved in attention, in representing spatial information, in performing arithmetic, and in many other activities; simply knowing

that these lobes are not activated to normal levels during a task does not tell us which particular processes they are failing to accomplish normally. Similarly, researchers don't know what it means when an area is activated when a person with a disorder performs a task but not when participants who don't have the disorder perform it.

Nevertheless, the outlook is far from hopeless. Researchers do know a considerable amount about what specific parts of the brain do (and are learning more every day). Also, they can use other techniques in combination with neuroimaging to learn which brain areas may play a role in causing or contributing to certain disorders. For example, if abnormal activation in the parietal lobe indicates that a person with schizophrenia is having to work harder to pay attention, then relatively low doses of transcranial magnetic stimulation (TMS) to the parietal lobe should disrupt the person's ability to pay attention more than would be the case for normal control participants. We will have more to say about neuroimaging research in subsequent chapters.

Challenges in Researching Psychological Factors

Scientists who study neurological factors examine the difficulties with the biological *mechanisms* that process information or that give rise to emotion. In contrast, scientists who study psychological factors examine specific mental contents, mental processes, behaviors, or emotions. As we noted in Chapter 3, information about psychological factors typically is obtained from patients' self-reports, from reports by others close to patients, or from direct observations.

Biases in Mental Processes That Affect Assessment

Assessing mental contents, emotions, and behaviors via self-report or report by others can yield inaccurate information because of biases in what people pay attention to, remember, and report. Sometimes beliefs, expectations, or habits bias how participants respond, consciously or unconsciously. For instance, people who have anxiety disorders are more likely to be extremely attentive to stimuli that might be perceived as a threat (Cloitre et al., 1994; Mathews et al., 1989; Mogg, Millar, & Bradley, 2000). In contrast, people with depression do not have this particular bias but tend to be biased in what they recall—they are more likely than people who are not depressed to recall unpleasant events (Blaney, 1986; Murray, Whitehouse, & Alloy, 1999; Watkins, 2002; Williams et al., 1997). In fact, researchers have found that people in general are more likely to recall information consistent with their current mood than information that is inconsistent with their current mood (referred to as *mood-congruent memory bias*; Teasdale, 1983).

Biases not only influence attention and recall, but also can affect reporting. In one study, college students completed tests of cognitive abilities (including memory) and then were asked to complete a self-report scale to indicate how depressed they were. Participants who were more depressed *reported* that their cognitive functioning was impaired, but their cognitive test results did not support their reports (Wong, Wetterneck, & Klein, 2000): Their subjective experience was at odds with objective data. Thus, biases in attention, memory, and reporting can distort the results of research.

Research Challenges with Clinical Interviews

Patients' responses can be affected by whether they are asked questions by an interviewer or receive them in a written questionnaire (see Figure 5.4). Consider a study in which participants were asked questions about their symptoms of either OCD or social phobia. When the questions were first asked by a clinician as part of an interview, participants tended not to report certain avoidance-related symptoms that they later did report on a questionnaire. In contrast, when participants completed the questionnaire first, they reported these symptoms both on the questionnaire and in the subsequent interview (Dell'Osso et al., 2002).

Moreover, when interviewing family members or friends about a patient's behavior, clinicians should keep in mind that these people may have their own biases. They may pay more attention to, and so be more likely to remember, particular

Myrleen Ferguson Cate/Photo Edit

People with different disorders tend to have different biases in what they pay attention to, remember, and report. A man with depression, for instance, might report that he's not doing a very good job at work, but this may not be accurate. Because of his depression, he is more likely to remember aspects of his performance at work that did not meet his expectations and to forget about aspects of his performance that met or surpassed his expectations.

aspects of a patient's behavior, and they may have their own views as to the causes of the patient's behavior (Achenbach, 2008; Kirk & Hsieh, 2004). For example, when assessing children, clinicians usually rely heavily on reports from others, such as parents and teachers; however, these individuals often do not agree on the nature or cause of a child's problems (De Los Reyes & Kazdin, 2004).

In addition, some people, because of their level of intelligence, attention span, or life experiences, misunderstand the intent of questions on a questionnaire or in an interview. For instance, the question "What have you done today?" could refer to what important activities were accomplished (e.g., writing a paper or giving a presentation), or it could have a more literal meaning—"Tell me everything you've done today," including taking a shower and dressing (Schwarz, 1999). Responses to different meanings of a question will affect the data. One advantage of an interview is that the clinician can rephrase a question if the patient responds in a way that reveals that he or she misunderstood the intended meaning.

Research Challenges with Questionnaires

In psychopathology research, questionnaires are a relatively inexpensive way to collect a lot of data quickly. However, questionnaires must be designed carefully in order to avoid various biases. For example, one sort of bias arises when a range of alternative responses are presented. Some questionnaires provide only two choices in response to an item ("yes" or "no"), whereas other questionnaires give participants more than two choices, such as "all the time," "frequently," "sometimes," "infrequently," or "never." With more choices comes more opportunities for bias: Twice a week might be interpreted as frequent by one person and infrequent by another. Moreover, the way the scale is defined is important. An example of this type of problem arose when people were asked to rate how successful they have been in life; simply changing the numeric values of the end points on the scale changed people's responses. When asked to respond on a rating scale with numbers from -5 to +5, like this:

34% reported having been highly successful in life. When asked to respond on a scale with numbers from 0 to 10, like this:

only 13% reported having been highly successful in life (Schwarz, Knäuper, Hippler, Noelle-Neumann, & Clark, 1991). To reduce the subjective aspect of rating scales, some questionnaires, such as the Posttraumatic Diagnostic Scale (Foa et al., 1997), define the frequency choices in terms of specific numerical values (such as having "frequently" defined as three times a week).

In addition, *response bias* is a major problem to avoid when designing questionnaires. **Response bias** refers to a tendency to respond in a particular way, regardless of what is being asked by the questions. For instance, some people, and members of some cultures in general, are more likely to check off "agree" than "disagree,"

Figure 5.4

5.4 ► How the Question Is Asked Affects the Answer

Patients may respond differently to a question, depending on whether it is part of a questionnaire or asked by an interviewer (Dell'Osso et al., 2002).

Response bias

The tendency to respond in a particular way, regardless of what is being asked by the question.

regardless of the content of the statement (Javeline, 1999; Welkenhuysen-Gybel, Billiet, & Cambré, 2003). This type of response bias, called *acquiescence*, can be reduced by wording half the items negatively. Thus, if you were interested in assessing self-reported shyness in a questionnaire, you might include both the item “I often feel shy when meeting new people” and the item “I don’t usually feel shy when meeting new people,” which is simply a negative rewording of the first item.

Another type of response bias is **social desirability**: answering questions in a way that the respondent thinks makes him or her “look good” (that is, in a way that he or she thinks is socially desirable), even if the answer is not true. For instance, some people might not agree with the statement “It is better to be honest, even if others don’t like you for it.” However, they may think that they *should* agree and respond accordingly. In contrast to a social desirability bias, some people answer questions in a way that they think makes them “look bad” or look worse than they actually are. People with malingering and factitious disorder (see Chapter 3) are likely to respond so that they appear more ill than they are. To compensate for these biases, many personality inventories have a scale that assesses the participant’s tendency to answer in a socially desirable or falsely symptomatic manner. This scale is then used to adjust (or, in the language of testing, to “correct”) the scores on the part of the inventory that measure traits.

Another type of response bias can occur because people generally assume that the center of the response scale is average. If a response scale is set up so that individuals believe that their responses are above (or below) average, they may shift their responses so that they are closer to average; see Figure 5.5 (Schwarz, 1999).

Figure 5.5

Low-Frequency Scale					
()	()	()	(X)	()	()
Less than once a month	About once a month	About once in two weeks	About once a week	About twice a week	More often
High-Frequency Scale					
()	(X)	()	()	()	()
Less than twice a week	About twice a week	About four times a week	About six times a week	About once every 24 hours	More often

5.5 ▸ High- and Low-Frequency Scales Depending on where someone’s response falls on a low- or high-frequency scale, the person may shift the response closer to the assumed average—the center.

Source: Schwartz, 1999. Copyright © 1999 American Psychological Association. For more information see the Permissions section.

Social desirability

A bias toward answering questions in a way that respondents think makes them “look good” (i.e., that he or she thinks is socially desirable), even if the responses are not true.

Challenges in Researching Social Factors

Challenges in researching social factors not only affect what can be learned about such factors themselves, but also affect what can be learned about other sorts of factors. Information obtained from and about people always has a context. For research on psychopathology, a crucial part of the context is defined by other people. Social factors arise from the setting (such as a home, hospital, outpatient clinic, or university),

the people administering the study, and the cultural context writ large. Challenges to conducting research on social factors that affect psychopathology include the ways that the presence or behavior of the investigator and the beliefs and assumptions of a particular culture can influence the responses of participants.

Investigator-Influenced Biases

Like psychological factors, social factors are often assessed by self-report (such as patient's reports of financial problems), reports by others (such as family members' descriptions of family interactions or of a patient's behavior), and direct observation. Along with the biases we've already mentioned, the social interaction between investigator and participant can affect these kinds of data.

Experimenter Expectancy Effects

Experimenter expectancy effect refers to the investigator's intentionally or unintentionally treating participants in ways that encourage particular types of responses. The experimenter expectancy effect is slightly misnamed: it applies not only to experiments, but also to all psychological investigations in which an investigator interacts with participants. For instance, suppose that you are investigating whether a particular symptom of social phobia—a fear of being in social situations with strangers—is associated with a particular symptom of OCD—recurring intrusive thoughts or images. You are investigating whether these two symptoms—each of a different disorder—are correlated. You interview participants with social phobia and ask them about the nature of their fears. When they mention symptoms that are not of interest to you (such as their preference to be alone), you ask about how they feel in social situations with strangers. It's possible that you might ask with a particular tone of voice or facial expression, unintentionally suggesting the type of answer you hope to hear. Participants might, consciously or unconsciously, try to respond as they think you would like, perhaps exaggerating certain symptoms a bit. Such a social interaction can undermine the validity of the study.

Reducing Experimenter Expectancy Effects with a Double-Blind Design

To minimize the likelihood of experimenter expectancy effects, researchers often use a **double-blind design**: Neither the participant nor the investigator's assistant (who has contact with the participant) knows the group to which the participant has been assigned or the predicted results of the study. That is, both are blind to the participant's group assignment and the predicted results. Implementing double-blind designs has the following features:

- First and foremost, the assistant, who does not know the predictions, collects the information from participants.
- The investigator eliminates cues in the environment that might allow the assistant to infer the predictions.
- Instructions given to participants or questions asked of them are standardized, so that all participants are treated in the same way.
- A computer or other automated device delivers instructions and stimuli and scores the responses.

Although double-blind studies are a way to minimize experimenter expectancy effects, participants try to make sense of what is being asked of them in a study despite an investigator's best efforts. Participants often develop their own hypothesis about the nature of the study and may behave accordingly (Kihlstrom, 2002a).

Reactivity

Have you ever had the experience of being watched while you were doing something? Did you find that you behaved somewhat differently simply because you knew that you were being observed? If so, then you have experienced **reactivity**—a behavior change that occurs when one becomes aware of being observed. When participants in a study know that they are observed, they may subtly (or not so subtly) change their behavior, leading the study to have results that may not be valid. One way to counter such an effect is to use hidden cameras, but this may raise ethical issues—many people (rightfully) object to being “spied on.”

Experimenter expectancy effect

The investigator's intentionally or unintentionally treating participants in ways that encourage particular types of responses.

Double-blind design

A research design in which neither the participant nor the investigator's assistant knows the group to which specific participants have been assigned or the predicted results of the study.

Reactivity

A behavior change that occurs when one becomes aware of being observed.

Although reactivity may be decreased by observing participants via video camera, they can still be aware that they are being observed by others and modify their behavior accordingly.

Reactivity can also occur when investigators observe family functioning. Suppose you were studying interaction patterns in families in which a parent is depressed. If the family members know that they are being observed (or at least the parents do), it is possible that this will change their behavior. Simply by giving you permission to observe their behavior, they may subtly change what they do and say. Thus, the behavior you observe may end up being different than it otherwise would have been.

Effects of Community Standards on Individual Behavior

Different communities can have different views of what thoughts, feelings, and behaviors are “normal” and “abnormal.” These community views, or *standards*, in turn affect individuals’ thoughts, feelings, and behaviors. However, as we have discussed earlier in this book, behavior that is

“normal” in one context may not be so in another. Researchers and clinicians recognize the influence that community and cultural context can create and try to address these effects. For example, some widely administered tests, such as the MMPI-2, provide different norms on the basis of age, gender, ethnicity, education level, and occupation, against which individual participants can be compared. Such norms then allow researchers to compare study participants to the population from which they were drawn.

Cultural Differences in Evaluating Symptoms

Some researchers compare and contrast a given disorder in different cultures. Such studies can help distinguish universal symptoms from symptoms that are found only in certain cultures. Consider that some people in every culture may develop phobias, and so they fear specific stimuli or circumstances, but which particular specific stimuli or circumstances they fear tends to vary across cultures. For instance, people in India are twice as likely as people in England to have phobias of animals, darkness, and bad weather (types of *specific phobias*, discussed in Chapter 7), but are only half as likely to have phobias related to social matters (Chambers, Yeragani, & Keshavan, 1986).

Assessing psychological or social factors in other cultures can be challenging for researchers. Many words and concepts do not have exact equivalents across languages, making full translation impossible. Even when two cultures share a language, the meaning of a word may be different in each culture. For example, when a comprehensive set of interview questions was translated into Spanish and administered to residents of Puerto Rico and Mexico, 67% of the questions had to be changed because the meanings of some of the Spanish words were understood differently by the two populations (Kihlstrom, 2002b).

Key Concepts and Facts About Research Challenges to Understanding Abnormality

- Many studies that focus on neurological factors are correlational and so do not reveal how neurological factors may give rise to psychological disorders. They reveal only that certain neurological factors are associated with some disorders.
- Neuroimaging studies are becoming more common, and these studies may indicate differences in brain structure or function between those with a psychological disorder and those without a disorder. However, it is not always clear how such differences contribute to a disorder.
- Self-reports of patients or reports by others may be biased in what is paid attention to, remembered, or reported. In addition, participants may respond differently to questions that are asked during an interview and those that are presented on a questionnaire. Moreover, participants may misunderstand the intent of a question and hence answer in way that distorts the results. Researchers must take care in phrasing questions in order to minimize misinterpretation and various types of biases.
- Challenges in studying social factors can also create challenges in studying other types of factors. Such challenges include experimenter-influenced biases, such as experimenter expectancy effects (which can be reduced with a double-blind design) and reactivity. A major challenge for cross-cultural research on psychopathology is the difficulty of translating words or concepts across cultures.

Researching Treatment

Let's say that your interest in depression following breakups, plus your experiences at the counseling center helping students like Carlos, have led you to develop a new short-term treatment. In this treatment, which you have named "grief box therapy," you encourage patients to create "grief boxes"—boxes into which they place reminders of their recently ended relationships, and objects that symbolize their feelings of loss and hopelessness. Moreover, as part of the treatment, you strongly encourage patients to be with other people—friends, family members, or coworkers—as much as possible to counteract their feelings of loss. You—and other clinicians—will want to know whether your treatment is effective; that is, is it better for treating depression (specifically the sort following a breakup) than other treatments? What specific questions might you want to ask that research can help to answer? Research on treatment helps mental health professionals decide what treatments to use with a given patient who has a particular disorder.

As you will see in the following sections, research on treatment has challenges above and beyond those we've already discussed for research on psychopathology. And such research faces different challenges, depending on whether the target of treatment is neurological, psychological, or social factors.

Researching Treatments That Target Neurological Factors

Researchers and clinicians want to answer several questions when a new medication is developed, when an existing medication is used in a new way (to treat different symptoms), or when a new biomedical procedure is developed:

- Is the new treatment more effective than no treatment?
- If a treatment is effective, is it because of its actual properties (such as a medication's particular ingredients) or because of patients' expectations about what the treatment will do?
- Is the treatment more effective than other treatments currently used for those symptoms or problems?
- What are the treatment's side effects, and are they troubling enough that patients tend to stop the treatment? How does this dropout rate compare to that for the other treatments?

To assess a treatment, researchers first need to determine what specific variables should be measured and to define what it means to be "effective." Research on treatment frequently relies on an experimental or quasi-experimental design; in such studies, the independent variables might be the type of treatment, a specific technique, or type or dose of medication. And the dependent variables (the things measured) might be any of the variables listed in any column of Table 4.1 (on page 114), such as neural activity, specific mental contents, or family functioning. These variables are often related to the symptoms listed in the DSM-IV-TR criteria for the disorder under investigation.

Drug Effect or Placebo Effect?

One way to determine whether a treatment is effective is to compare it to no treatment. If people receiving the treatment are better off than those who don't receive any treatment, the treatment may have made the difference. But with biomedical treatments, such a comparison has a built-in problem: Patients know whether or not they have received the treatment. Perhaps people improve after taking a medication (or after ECT, TMS, or some other procedure) not because of the properties of the treatment itself, but because they expect to improve after receiving treatment. In fact, many studies have confirmed that expecting a treatment to be helpful leads to improvement, even if the individuals don't receive any actual treatment (Kirsch & Lynn, 1999). For example, having a TMS coil pressed on the scalp

Placebo effect

A positive effect of a medically inert substance or procedure.

Attrition

The reduction in the number of participants during a research study.

Nathan Griffith/Corbis

The color of a placebo pill can influence how effective it is. Red, pink, and yellow placebo pills work best when people believe them to be “stimulants,” whereas blue placebo pills work best when people believe them to be “tranquilizers” (Buckalew & Ross, 1981).

and hearing loud clicking noises (like those produced during TMS when a magnetic field is discharged) can affect symptoms, whether or not magnetic pulses are actually sent to the brain (Loo, 2004; Nahas et al., 2003).

To discover whether a biomedical treatment is effective, researchers give a group of participants a *placebo*, an inert substance or a procedure that itself has no direct medical value. Often, a placebo is simply a sugar pill. A positive effect of such a medically inert substance or procedure is called a **placebo effect**. If patients who are given a sugar pill show the same improvement as patients who are given the pill with active ingredients, then a researcher can infer that the medication itself is not effective and that its apparent benefit is a result of the placebo effect.

The placebo effect can be strengthened or weakened by the outward qualities of the placebo and how it is administered: Taking more placebo pills generally has a greater effect; capsules do a better job than pills; and injections do better than capsules. The placebo can have an even greater effect when the person dispensing it shows interest in the patient’s problems and is sympathetic and friendly (Shapiro & Morris, 1978). And placebos that patients are told cost more are more effective than are “less expensive” ones (Waber et al., 2008). If a study is not double-blind, an investigator’s high expectations of a treatment’s success also can cause a positive placebo effect (Shapiro, 1964). (In double-blind studies on treatment, the mental health clinician administering the treatment—as well as the patient—is blind to the patient’s group assignment.

Thus, when investigators test the effects of any new medicine or other biomedical treatment, they invariably use some type of placebo treatment as a comparison. They may also include additional comparison groups, in which patients receive more established treatments, and researchers will likely use a double-blind design. Not all researchers are convinced, however, that patients and clinicians are truly “blind” in double-blind studies. In double-blind studies of medications for depression and anxiety, for instance, both patients and (“blind”) clinicians may correctly guess whether patients are receiving a placebo or active medication based on the presence of side effects and changing symptoms (Margraf et al., 1991; White et al., 1992).

Some researchers have suggested that in order to evaluate the results of double-blind studies of medication, investigators should determine whether patients and their clinicians were actually blind to the treatment that the patients received (Piasecki et al., 2002); if not, the investigators should not consider the study to have been truly double-blind. Furthermore, some researchers also advocate using an *active placebo*—a placebo that mimics the side effects of an active medication but does not directly affect the psychological symptoms of the disorder being treated (Kirsch, Scoboria, & Moore, 2002; Moncrieff, 2001). For instance, when studying the effects of a tricyclic antidepressant, an investigator might use as an active placebo an antihistamine—an over-the-counter cold medicine that has some side effects that are similar to those of tricyclics.

The fact that people who suffer from certain disorders, including depression, sometimes improve following a placebo treatment (Kirsch, Scoboria, & Moore, 2002) does not mean that their problem was imaginary, or that they should throw away their medication. Rather, it seems that—for some people and for some disorders—the hope and positive expectations that go along with taking a medication (or undergoing a procedure) allow the body to mobilize its own resources to function better (Kirsch & Lynn, 1999; Scott et al., 2008).

Dropouts

On average, more than half of those who begin a treatment that is part of a research study do not complete the treatment—they drop out of the study (Kazdin, 1994). The reduction in the number of research participants during a study is called **attrition**. When attrition is different for different groups in a research study, researchers can’t easily draw definitive conclusions about the treatment given to one group (Kendall, Holmbeck, & Verduin, 2004; Lambert & Ogles, 2004). Suppose, for example, that a group receiving medication (and experiencing its side effects)

has more attrition than a group receiving a placebo (and not experiencing any side effects). To determine the medication’s effects, should the researcher compare the placebo group to all those who *started* in the medication group (and thus include those who dropped out of the study), or should the researcher compare the placebo group only to those who *completed* the medication treatment? If you compare those who took the placebo to those who completed the medication treatment, the medication might look very promising. But if you compare the placebo group to all those who started the medication, the medication might not appear more effective than the placebo. This question of whether to include the results of those who drop out applies to research on all types of treatment—it isn’t limited to research on biomedical treatments.

Researching Treatments That Target Psychological Factors

Many of the research issues that arise with biomedical treatments also arise in research on treatments that target psychological factors. In addition, as shown in Table 5.3, research on treatments that target psychological factors may be designed to investigate which aspects of therapy in general, or of particular types of therapy—such as your grief box therapy—are most helpful. Let’s consider the sorts of factors that underlie the effects of treatments that targets psychological factors, how researchers control for confounding factors when they study such treatments, whether therapy is better than no treatment, whether one type of therapy is generally best, and which types of therapy are better for treating specific disorders.

Table 5.3 ▶ Treatment-Related Variables

Therapy Variables	Patient Variables	Therapist Variables	Patient-Therapist Interaction Variables
<ul style="list-style-type: none">• Theoretical orientation• Specific techniques used	<ul style="list-style-type: none">• Level of motivation and ability to change• Belief in the ability of treatment to help• Community resources available (social and financial support)• Preferred style of coping and relating to others• Preferred treatment focus: on symptoms (as in CBT) or on their meaning (as in psychodynamic therapy)• Personality traits	<ul style="list-style-type: none">• Enthusiasm for and belief in the treatment• Usual style of interacting (such as supportive or challenging)• Treatment focus: on symptoms or on their meaning• Empathic ability• Personality traits• Experience with the particular type of treatment	<ul style="list-style-type: none">• Structure of the relationship (therapist as expert vs. therapist as coach)• Fit between patient’s and therapist’s personalities• Fit between patient’s and therapist’s treatment focus (symptoms vs. their meaning)• Sense of alliance between patient and therapist

Common Factors

Just as placebos can provide relief even though they lack medically beneficial ingredients, the very act of seeing a therapist or counselor—or even setting up a meeting with one—may provide relief for some disorders (regardless of the specific techniques or theoretical approach of the therapist or counselor). Such relief may be due, at least in part, to **common factors**, which are helpful aspects of therapy that are shared by virtually all types of psychotherapy. According to results from numerous studies (Garfield & Bergin, 1994; Lambert & Ogles, 2004; Weinberger, 1995), common factors can include:

- opportunities to express problems;
- some explanation and understanding of the problems;

Common factors
Helpful aspects of therapy that are shared by virtually all types of psychotherapy.

- an opportunity to obtain support, feedback, and advice;
- encouragement to take (appropriate) risks and achieve a sense of mastery;
- hope; and
- a positive relationship.

Common factors, and certain patient characteristics—such as being motivated to change (Clarkin & Levy, 2004)—can contribute more to having a positive outcome from therapy than the specific techniques used. This means that Carl Rogers was on to something when he stressed the importance of a therapy relationship that is supportive and warm. Such qualities can amplify the therapeutic power of the common factors; however, the magnitude of the effect of common factors depends on the patient's specific problem (Roth & Fonagy, 2005). If your grief box therapy were effective, it might be because of such common factors and not something unique to your particular method.

Specific Factors

The existence of common factors creates a challenge for researchers who are interested in determining the benefits of a particular type of treatment or technique. These researchers must design studies in which the effects of common factors are accounted for and the unique benefits of the particular treatment or technique under investigation can be examined. The characteristics that give rise to these unique benefits are known as **specific factors**. For instance, when researching your grief box therapy, you might want to investigate whether the process of creating the grief box is a specific factor, providing benefit above and beyond the common factors that any therapy provides.

Such research has shown that common factors alone may not be *sufficient* to produce benefits in therapy for some disorders (Elliott, Greenberg, & Lietaer, 2004; Kirschenbaum & Jourdan, 2005; Lambert, 2004); at least for some disorders, specific factors play a key role in treatment. For example, research results suggest that for people with OCD, exposure with response prevention (a specific factor) is more important for successful treatment than common factors (Abramowitz, 1997; Chambless, 2002). However, for many disorders, including depression, the research results suggest that specific factors may be only as important as (or even *less* important than) common factors in the treatment of mild or moderate cases (Lambert, 2004). In fact, for some disorders, researchers have found that different types of therapy are about equally beneficial. The leftmost column in Table 5.3 notes specific factors—the therapy variables—that are the subject of research targeting psychological treatments. (In subsequent chapters, we will discuss research on treatments for specific disorders; such studies typically examine specific factors.)

Controlling Possible Confounding Variables with Analogue Studies

Many variables, such as those listed in Table 5.3, can influence the outcome of psychotherapy and may be confounding variables in specific studies. For instance, suppose you decide to undertake a study that compares your grief box therapy for depression after breakups to an older treatment for depression, such as cognitive-behavior therapy (CBT); you train some therapists at the counseling center to administer your new treatment, and they are very excited and enthusiastic about it. Other therapists at the counseling center administer CBT for depression, which they've been providing for years. These therapists may be less enthusiastic in their manner during therapy. If your new therapy does in fact benefit patients more than does CBT, a possible confounding variable would be the therapists' levels of enthusiasm for the two treatments. That is, it could be the manner in which the new therapy was provided that was particularly helpful to patients rather than the technique itself.

Specific factors

The characteristics of a particular treatment or technique that lead it to have unique benefits, above and beyond those conferred by common factors.

One way to study specific factors and also control for possible confounding factors that might influence treatment results is to carry out an analogue study. An **analogue study** is a type of research on treatment that is conducted under controlled conditions in a laboratory setting, thereby minimizing confounds. It is called an analogue study because the therapy is provided in a way that is *analogous* to the way therapy is usually provided. For example, one analogue study on family therapy sought to determine which method of questioning family members best facilitated each member's sense of alliance with the family therapist (Ryan & Carr, 2001). In this study, participating family members watched four 5-minute video clips of simulated family therapy sessions. In each clip, the therapist and family members remained the same; the clips differed only in the way the therapist questioned the family. Participants were asked to rate their perceptions of the alliances between the family members and the therapist in each of the four clips. Because the participants responded to video clips of simulated therapy sessions rather than directly experiencing different styles of asking questions (as would patients in actual family therapy sessions), the researchers could control for factors other than the therapist's style of questioning.

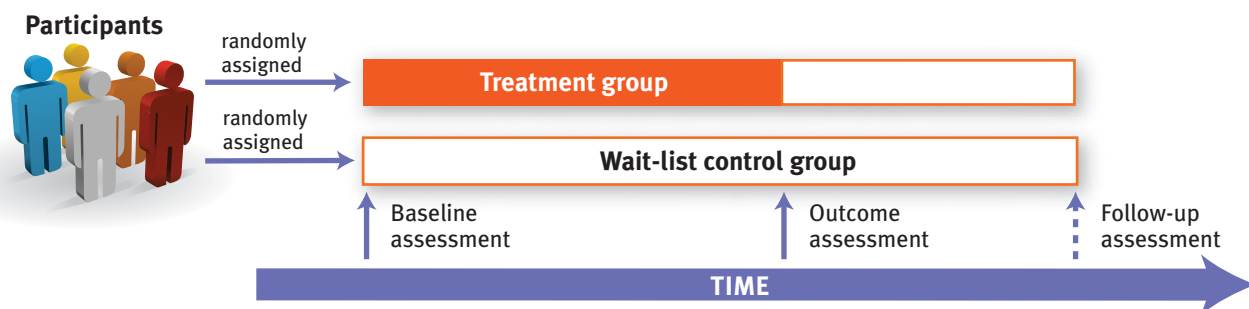

Analogue study

Research in which treatment is provided in a way that is analogous to the way it is usually provided, but that is conducted under controlled conditions in a laboratory setting, thereby minimizing confounds.

Is Therapy Better Than No Treatment?

Many kinds of treatments have been proposed for various disorders, but researchers have questioned whether people actually improve more by receiving therapy than they would have improved if they didn't receive any treatment. To address this question, researchers randomly assign participants to one of two groups: "treatment" and "no treatment." However, participants in the "no treatment" group are often assigned to a waiting list for treatment (which is ethically preferable to not providing any treatment at all), and thus this group is often called a *wait-list control group* (Kendall, Holmbeck, & Verduin, 2004, Lambert & Bergin, 1994). Researchers usually assess the dependent variable, such as level of symptoms, in both groups at the beginning of the study, before treatment begins—this is their *baseline assessment*. Then, researchers assess the same variables again after the treatment period (for the wait-list control group, this means assessing symptom level after the same duration of time as that over which the treatment group received treatment); this is called the *outcome assessment*. Researchers then compare the results of the two groups, and may also assess the variables at a later follow-up point, called a *follow-up assessment* (see Figure 5.6).

Figure 5.6

5.6 ▶ Comparing a Treatment Group to a Wait-List Control Group Participants are randomly assigned to one of two groups, a treatment group and a wait-list control group (although a study could have more than two groups). Generally, the dependent variables, such as intensity of symptoms, are assessed before the treatment period begins, to obtain a baseline. After treatment ends (or after the equivalent number of weeks for the wait-list control group), the dependent variables are again assessed (and may also be assessed later for follow-up) and the data from the two groups are compared.

Initially, studies designed to test the overall superiority of one form of psychotherapy over another did not find one type of therapy to be more effective. This finding has been called the *Dodo bird verdict*, in reference to the Dodo bird's proclamation in *Alice's Adventures in Wonderland*: "Everybody has won and all must have prizes." However, the Dodo bird verdict was based on research of particular therapies available at that time, using less rigorous research methods than those generally used today (Beutler, 2000).

Mary Evans Picture Library/Alamy

Alternatively, instead of a “no treatment” or wait-list control group, researchers may use a placebo control group, the members of which meet with a “therapist” with the same frequency as the members of the treatment group. The “placebo therapist” refrains from using any of the active treatment techniques employed in the treatment group, but patients still receive attention and some level of support. For a study of your grief box therapy, a placebo control group might consist of patients who meet with therapists who listen to their concerns or complaints—without grief boxes, social support, or any other specific interventions.

With either type of control group—wait-list or placebo—researchers compare the level of symptoms in the treatment group with that in the control group before and after the treatment (or at equivalent times, if there was no treatment). It is possible that symptoms of members of the control group might diminish simply with the passage of time, and thus the crucial comparison is not whether people in the treatment group got better—but rather how much more they improved than did the people in the control group.

Researchers have conducted such studies for over half a century. How did they answer the question of whether therapy works? With a resounding “yes.” Therapy really does make a difference (Lambert & Ogles, 2004). And, not surprisingly, treatment shows a larger effect when a treatment group is compared to a wait-list control group than when a treatment group is compared to a placebo group, which highlights the beneficial effects of common factors (Lambert & Ogles, 2004; Roth & Fonagy, 2005). However, studies with a wait-list control only reveal that all the myriad factors that go into treatment are more effective than no treatment at all. This sort of research doesn’t identify which common factors or specific factors lead patients to improve (Borkovec & Miranda, 1999).

But what does it really mean to say that therapy works—that people who receive therapy are better off than those who don’t receive therapy? How much better off are they? This is a complex question, and researchers currently frame it in terms of *clinical significance*, which may be either statistically meaningful or clinically meaningful. Consider a woman with the eating disorder bulimia nervosa, which typically involves compulsively eating large amounts of food (more than just “pigging out”—such *bingeing* consists of eating well past the point of normal fullness) and then vomiting to try to prevent weight gain. Suppose that, prior to treatment, the woman was bingeing and vomiting daily, but after treatment she was doing so only three times a week. This reduction may be statistically meaningful (although her symptoms are still over the threshold of the DSM-IV-TR criteria for the disorder). But is it clinically meaningful—does this decrease in symptoms improve her daily functioning or other aspects of her quality of life (Kendall, Holmbeck, & Verduin, 2004)? Such assessments of clinical significance may be based on the patients’ own perceptions, on observations of friends and family members of the patients, or on the therapists’ judgment.

Is One Type of Therapy Generally More Effective Than Another?

With the advent of behavior therapy in the 1960s, some researchers asked whether one type of therapy is generally more effective than another. Researchers who addressed this question randomly assigned participants to one of two groups, which received two different types of treatment. Participants in the therapy groups were compared to each other at the end of treatment, and sometimes at some later point in time.

The initial results of such research were surprising: No type of therapy appeared more effective than another, a finding that has been called the *Dodo bird verdict* of psychotherapy (Luborsky, Singer, & Luborsky, 1975). In the book *Alice’s Adventures in Wonderland*, the Dodo Bird says: “Everybody has won, and all must have prizes.” In this first generation of psychotherapy research, researchers did not investigate what actually transpired in the therapy sessions or whether some types of treatment were more effective for particular disorders.

Is One Type of Therapy Better for Treating a Specific Disorder?

The first generation of research on treatment found that, in general, treatment of psychological disorders led to better outcomes compared to no treatment and no single treatment was superior to others. However, by the 1980s, a second generation of such research had begun, which examined both specific factors and specific disorders. This research sought to address whether any particular type of therapy was more effective than others in treating a specific disorder. (For instance, you would be addressing this question if you performed a study comparing your grief box therapy to CBT for people who became depressed after a breakup.) In order to address this research question, investigators refined the methods and procedures they used to provide therapy and assess its outcome. Let's briefly consider key advances in how researchers study the effects of various psychotherapies.

Randomized Clinical Trials

The second generation of research began with the landmark study by the National Institute of Mental Health (NIMH). The study was called the Treatment of Depression Collaborative Research Program (TDCRP; Elkin et al., 1985), and it marked a turning point in psychotherapy research. It used a research design analogous to the design used to measure the effect of a medication on symptoms of a medical disorder; this research design is referred to as a **randomized clinical trial (RCT)**; also referred to as *randomized controlled trial*). RCTs have at least two groups, a treatment group and a control group (usually a placebo control), and participants are randomly assigned to groups (Kendall, Holmbeck, & Verduin, 2004). RCTs may also involve patients and therapists at multiple sites in a number of cities.

Researchers who conduct RCTs seek to use the scientific method to identify the specific factors that underlie a beneficial treatment. The independent variable is often the type of treatment or technique, as it was in the TDCRP, or any other variable listed in Table 5.3. The dependent variable is usually some aspect of patients' symptoms—such as frequency or intensity—or quality of life.

The TDCRP was designed to compare the benefits of four kinds of treatment for depression given over 16 weeks: interpersonal therapy (IPT), CBT, the tricyclic antidepressant medication *imipramine* (which was widely used before SSRIs became available) together with supportive sessions with a psychiatrist, and a placebo medication together with supportive sessions with a psychiatrist. Various dependent variables were measured. The main results told an interesting story: At the 18-month follow-up assessment, the CBT group had a larger sustained effect and fewer relapses, especially compared with the imipramine group (Elkin, 1994; Shea et al., 1992). But when the most severely depressed patients in each group were compared, IPT and imipramine were found to have been more effective than CBT (Elkin et al., 1995). However, most important in this study, the quality of the “collaborative bond” between therapist and patient (which was assessed by independent raters who viewed videotapes of sessions) had a stronger influence on treatment outcome than did the type of treatment (Krupnick et al., 1996).

The Importance of Follow-up Assessment

The TDCRP study followed patients for over 18 months after treatment ended, but some studies—because of financial or logistical constraints—do not make any follow-up assessment. This is unfortunate because the follow-up assessment imparts information about the enduring effects of treatment. One type of treatment may be more beneficial at the end of therapy, but those patients may have a higher rate of relapse a year later, leaving the patients in the other treatment group better off in the long run (Kendall, Holmbeck, & Verduin, 2004). Moreover, it is through follow-up assessments that investigators are best able to identify those at risk for relapse and learn how best to adjust treatment in order to help patients maintain their gains over the long term (Lambert & Ogles, 2004).

Randomized clinical trial (RCT)

A research design that has at least two groups—a treatment group and a control group (usually a placebo control)—to which participants are randomly assigned.

Exclusion Criteria

In most RCTs, including the TDCRP, researchers investigate treatments for patients who have a “pure” form of the DSM-IV-TR disorder of interest (Goldfried & Wolfe, 1998)—and *only* that one disorder. The decision to exclude people with an additional disorder or disorders makes many patients ineligible to participate. In reality, however, most patients have more than one disorder, which raises external validity questions about research using this exclusion criteria. In fact, after treatment, people with multiple disorders do not usually make the gains made by people who have only a single disorder (Coryell et al., 1988).

Manual-Based Treatment

One problem for researchers studying a particular type of therapy is that a therapist who claims to provide a particular type of therapy may in fact provide treatment that is remarkably similar to that of a therapist using a different theoretical orientation (Lambert & Bergin, 1994). This makes comparisons among types of therapies difficult. Suppose that some self-defined CBT therapists focus on relationship issues, and some self-defined IPT therapists give concrete suggestions for improving relationships. If there were no differences in outcomes between the two types of treatment, it could be because therapists in the two groups were all doing much the same thing!

In an effort to address this problem, RCTs generally require therapists to base their treatments on detailed manuals that provide session-by-session guidance and specify techniques to be used with patients. RCTs provide brief therapy, typically from 6 to 16 sessions. Different therapeutic approaches use different manuals; the most common theoretical approach for manual-based therapy is CBT. *Manual-based treatment* ensures that all therapists who use one particular approach provide similar therapy that is distinct from other types of therapy (Kendall, Holmbeck, & Verduin, 2004; Nathan, Skinstad, & Dolan, 2000).

Such research has led to more than 108 different treatment manuals for adults with 51 different DSM-IV-TR disorders (Beutler & Harwood, 2002; Chambless & Ollendick, 2001). Research aimed at identifying the unique specific components of a successful therapy has progressed by adding, subtracting, or otherwise changing specific components of a particular treatment manual, and then comparing the results from the two variations. For example, one RCT treatment group might receive CBT for depression, whereas another group would receive the same CBT *plus* an interpersonal component of treatment (similar to IPT). If patients in both groups fare the same, then the interpersonal component cannot be considered an active ingredient in this sort of treatment. Conversely, if the dual-component group fares better after treatment, then it can be inferred that the added interpersonal component made the treatment more effective. Similarly, to study your grief box therapy, you might have one group in which the members both make the boxes *and* reach out to friends and family and another group in which the members would only make the boxes without an emphasis on reaching out to friends and family.

In studies using this approach, the same therapist may perform both variants of a treatment (in contrast to earlier RCTs, in which a different group of therapists performed each type of therapy). By having each therapist perform different variants of treatment, researchers attempt to control for possible therapist variables that might affect treatment.

Allegiance Effect

Another issue in RCT research is the **allegiance effect**, in which studies conducted by investigators who prefer a particular theoretical orientation tend to obtain data that support that particular orientation (Luborsky et al., 1999). Specifically, RCT investigators who support one type of treatment tend to have patients who do better with that type of treatment, whereas patients in the same study (using the same

Ted Szczepanski/Worth Publishers

In order to ensure that the particular type of therapy under investigation is, in fact, the type of therapy that is provided in the session, researchers may have therapists use manuals that specify in detail the goals of each session and the methods to be used.

Allegiance effect

A pattern in which studies conducted by investigators who prefer a particular theoretical orientation tend to obtain data that supports that particular orientation.

manuals) whose investigators support a different type of treatment tend to do better with that treatment. This means that even the use of manuals is not enough to control all types of confounds completely.

Empirically Supported Treatments and Evidence-Based Practice

When well-designed and well-conducted research studies, particularly those that rely on RCTs, show that a particular treatment or technique for a given disorder has a beneficial effect, that treatment or technique is said to be *empirically supported* (also referred to as *empirically validated*; Kendall, Holmbeck, & Verduin, 2004; Task Force on Promotion and Dissemination of Psychological Procedures, 1995). That is, research results support its beneficial effect. However, note that treatments or techniques that aren't designated as empirically supported may be equally beneficial—researchers just may not yet have documented their effects.

Suppose Carlos comes back to the counseling center a year after you first saw him, this time because he's having test anxiety. He gets so anxious before a test that he ends up doing poorly on the test even though he knows the material cold. How can you know which type of treatment or set of techniques to use to help him? Ideally, you have an *evidence-based practice*; that is, for each patient, you pick a treatment or set of techniques that research has shown to be effective for that patient's problem. (Such a judgment should also take into account the therapist's preference for—and training in—a particular method.) In the case of treating anxiety, for instance, various CBT methods such as relaxation training, cognitive restructuring, and exposure have been found to be effective for treating anxiety (Ergene, 2003).

Criticisms of RCTs

Research using RCTs has a number of critics and cautious observers (Messer, 2004). Their criticisms, discussed below, also apply to empirically supported treatments and evidence-based practices that are largely based on RCTs (Westen, Novotny, & Thompson-Brenner, 2004, 2005):

- **Exclusion criteria.** Excluding patients with more than one disorder limits the generalizability of a study's results (Westen & Morrison, 2001). For example, more than half of those with an anxiety disorder have at least one additional disorder, and 30–40% of those with depression also have been diagnosed with a personality disorder (Sleek, 1997). Moreover, researchers have shown that comorbid disorders affect the efficacy of treatment. For instance, treatment gains are generally more modest for those who have a personality disorder in addition to an Axis I disorder (Clarkin & Levy, 2004).
- **Homogenous samples.** Most of the patients in RCTs are White and middle-class. It is not clear how well such treatments generalize to patients with other ethnic backgrounds and from other socioeconomic levels (Bernal & Scharró-del-Río, 2001). For example, when manual-based CBT—which was effective in an earlier RCT—was employed with depressed patients from an economically disadvantaged population, the treatment was not very effective (Miranda et al., 2003).
- **Overly rigid manual-based treatment.** Studies investigating the rigid use of manuals in RCTs suggest that strict adherence to manuals leads to less favorable results (Castonguay et al., 1996). Moreover, most therapists who are not part of a research study use manuals flexibly, if they use them at all. Thus, some critics ask, what knowledge is gained from RCTs that is applicable to the majority of therapists?
- **Therapy quality.** The quality of treatment in a RCT may vary even when the therapists are equally well trained and use the same manual, simply because therapists, as individuals, bring different levels of skill to their work (Garfield, 1998; Luborsky et al., 1997; Westen, Novotny, & Thompson-Brenner, 2005).
- **Common factors versus specific techniques.** For the treatment of some disorders, such as depression, the specific therapeutic approach or technique appears to contribute less toward successful therapy than do other factors, such as the quality of the therapist-patient relationship, the patient's motivation and readiness for change, and the alliance between therapist and patient (Horvath & Symonds,

Russell Sadur/Getty Images

Should a therapist use *aromatherapy*—having patients smell certain plant-based essential oils—to treat psychological disorders? Aromatherapy is not an empirically validated treatment for psychological disorders (Louis & Kowalski, 2002). This technique is in the realm of *pseudopsychology*, where claims are supported primarily by case studies or poorly designed studies with few participants, often without an appropriate control group.

Dose-response relationship

The association between more treatment (a higher dose) and greater improvement (a better response).

1991; Martin, Garske, & Davis, 2000; Messer, 2004; Messer & Wampold, 2002; Wampold, 2001). Thus, focusing on isolated components of treatment in an effort to enhance therapy may not be as effective as proponents had hoped. Moreover, RCTs generally do not assess patient variables, therapist variables, and patient-therapist interaction variables (Table 5.3), which may be important specific factors related to successful treatment (Beutler & Karno, 1999). For instance, those with more severe symptoms generally respond less well to treatment than do those with less severe symptoms, and those who are motivated to change make more positive change than do those less motivated (Clarkin & Levy, 2004; Garfield, 1994).

- *Length of treatment.* RCTs use short-term therapy, which may not be comparable to the type of therapy provided by most therapists. Moreover, research indicates that patients who have problems in only one sphere of life (for example, at work) receive greater benefit from brief psychotherapy than do those with problems in multiple spheres of life (Barkham & Shapiro, 1990; Klosko et al., 1990; Strupp & Binder, 1984)—perhaps in part because when a patient has problems in multiple spheres, fewer sessions are devoted to problems in each sphere.
- *Problems with DSM diagnostic groups.* We discussed some of the criticisms of DSM-IV-TR diagnostic groups in Chapter 3. Many of these criticisms also arise in the context of RCTs. For instance, it is possible that two people with the same disorder (according to DSM-IV-TR criteria)—but with different sets of symptoms—may respond differently to different treatments (Duncan, 2002).
- *Dependent variables.* What are appropriate dependent variables? Different types of therapy might be more (or less) effective with each of the variables listed in Table 5.3. Some RCTs focus exclusively on symptoms that pertain to DSM-IV-TR criteria. Perhaps treatments (or components of treatments) that reduce symptoms are different from those that improve relationships or quality of life. To the extent that researchers assess only DSM-IV-TR symptoms, such additional information will not be discovered.
- *Applying the results to individual patients.* Data from groups may not apply to a given individual sitting in a clinician's office. Each person has a unique background and a unique set of abilities, skills, and interests. In choosing a type of treatment for a given patient, clinicians often rely on their own experiences with similar patients (Pilkonis & Krause, 1999).

Some of the criticisms of RCTs—and therefore of empirically supported treatments—can be summed up by noting the difference between a treatment's *efficacy* and a treatment's *effectiveness*. Efficacy is assessed within the carefully controlled confines of RCTs in a research clinic. Effectiveness is assessed in nonresearch settings, the place where most clinicians treat patients, without excluding them because of multiple diagnoses. Thus, a treatment's effectiveness refers to the question of its generalizability to real-world settings, with no exclusion criteria, no set number of sessions, and usually no treatment manual (Kendall, Holmbeck, & Verduin, 2004; Lambert & Ogles, 2004; Roth & Fonagy, 2005). RCTs and evidence-based practices may overemphasize differences in technique among treatments while underemphasizing other factors that affect outcomes, such as the patient-therapist alliance and other common factors (Wampold & Bhati, 2004).

Table 5.4 ► Ethical Guidelines for Research on Experimental Treatments

Psychologists conducting research on experimental treatments must clarify to participants at the outset of the research:

- (1) the experimental nature of the treatment;
- (2) the services that will or will not be available to the control group(s) if appropriate;
- (3) the means by which assignment to treatment and control groups will be made;
- (4) available treatment alternatives if an individual does not wish to participate in the research or wishes to withdraw once a study has begun; and
- (5) compensation for or monetary costs of participating.

Ethical Research on Experimental Treatments

Any research on treatment conducted by a psychologist is bound by the ethical guidelines for research and usually must be approved by an IRB, discussed earlier in the chapter. As shown in Table 5.4, research on a new type of treatment—an *experimental* treatment such as your grief box therapy—is subject to additional guidelines because the researchers may not be aware of some of the risks and benefits of the new treatment at the outset of the study.

The Therapy Dose-Response Relationship

We have been discussing research on treatment that uses experimental designs, randomly assigning participants to two or more groups and then comparing the results. Another approach relies on correlational methods. By definition, correlational studies of treatment do not include random assignment, nor do they have independent or dependent variables. Rather, a correlational research study determines whether changes in one variable are associated with changes in another variable.

Correlational research can answer a question like this: Is more treatment related to greater improvement? In other words, is a higher “dose” of therapy (more sessions) associated with a better “response”? This association between dose and response is referred to as the **dose-response relationship**, and research suggests that the general answer to this question is yes. More sessions are associated with a better outcome (Hansen, Lambert, & Forman, 2002; Shadish et al., 2000). In general, patients improve the most during the early phase of treatment (see Figure 5.7), and they continue to improve, but at diminishing rates, over time (Lutz et al., 2002). There are individual exceptions to this general pattern, as when someone with a specific phobia has an extremely good response to a single session of exposure therapy (Hellström & Öst, 1995; Öst, Grandberg, & Alm, 1997; Öst et al., 2001). However, people with more severe or entrenched problems, such as schizophrenia or personality disorders, may not show as much benefit in the early stages of outpatient treatment but rather tend to improve over a longer period of time.

Because the dose-response relationship is correlational, it does not indicate whether the increased number of sessions *causes* the increased response. It is possible that people who are feeling better during the course of treatment are more eager or more willing to attend additional sessions than those who are not responding as well. If this were the case, the response would be “causing” the increased dose

Figure 5-7

Among 10,000 patients with various psychological disorders, half attained clinically significant improvement (that is, *recovery*) by the 21st session. Another 25% attained clinically significant improvement by the 40th session. However, most people in RCTs, or in therapy in general, receive far fewer than 40 sessions.

Examining data using a lower standard of improvement—any positive change that was stable over time—and including patients who started out able to function reasonably well despite their disorder, yields different results: Half the patients attained this lower standard of improvement by the 7th session, with another 25% “improved” by the 14th session (Lambert, Hansen, & Finch, 2001).

5.7 ▶ The Dose-Response Relationship Comparing a more stringent definition of “improvement” (Figure 5.7a) to a more liberal one (Figure 5.7b) makes it clear that the exact criteria for improvement determine the particular height and shape of the curve for the dose-response relationship.

A curious finding invites speculation: People in the eastern part of the United States remain in treatment longer than those in the western part (“Fee, Practice, and Managed Care Survey,” 2000). This is merely a correlation. One possible explanation is that people in the eastern part have a different definition of “improvement”; that is, they continue in treatment until their symptoms have improved more than those of their counterparts in the western part of the country. However, there are other possible explanations; perhaps you can think of some.

Spencer Grant/Photo Edit

Some patients prefer a therapist who shares their ethnic background, and this common background may make a patient less likely to drop out of treatment. However, such matching does not appear to produce better treatment outcomes (Beutler, Machado, & Neufeldt, 1994; Garfield, 1994; Lam & Sue, 2001).

(increased number of sessions) (Otto, 2002; Tang & DeRubeis, 1999). Alternatively, both dose and response could be affected by some other factor. For example, perhaps people who fare better as a result of treatment have more social support available in their lives, and these supportive individuals encourage them to continue treatment. As noted earlier in this chapter, correlation does not imply causation.

Researching Treatments That Target Social Factors

Research on treatment may also investigate the possible benefits of targeting social factors (for example, by matching patient and therapist by gender or ethnicity) or the ways in which treatment may be affected by the larger social context (including shared beliefs about a treatment's beneficial effects).

Matching Patient and Therapist by Gender and Ethnicity

All types of psychotherapy involve a relationship between two (or more) people. Therapists and patients may be similar with regard to racial or ethnic background and gender, or they may be different. Does such a difference matter? Research suggests not: Differences between patient and therapist in ethnicity, gender, and age do not systematically alter therapy's beneficial effect (Beutler, Machado, & Neufeldt, 1994; Fiorentine & Hillhouse, 1999; Garfield, 1994; Lam & Sue, 2001; Maramba & Hall, 2002). However, with regard to gender, one study found that women and men are both less likely to drop out of treatment if they have a female therapist, although the study did not address the reason for this gender preference (Flaherty & Adams, 1998).

Nevertheless, some people prefer a therapist with a similar ethnic or racial background to their own. For those with a strong preference, such as some Asian Americans, matching the ethnicity of the patient and therapist may lead to better outcomes (Sue, Zane, & Young, 1994), and it can result in lower dropout rates among non-Whites (Flaherty & Adams, 1998; Flaskerud & Liu, 1991; Fiorentine & Hillhouse, 1999; Sue, Kuraski, & Srinivasan, 1999). However, not all studies have reported this result (Arcia, Sanchez-LaCay, & Fernandez, 2002).

Research on psychotherapy across different ethnic groups is complex, in part because of possible confounding factors. For instance, ethnicity is often associated with other demographic variables, such as socioeconomic status. Moreover, a patient's preference for a therapist from the same ethnic group may suggest that it's important for the patient and therapist to share *values*, not the same ethnic background per se (Ito & Maramba, 2002; Karlsson, 2005; Wong et al., 2003). In addition, research suggests that the more culturally assimilated a patient from a nonmajority ethnic group is, the less patient-therapist matching matters (Alvidrez, Azocar, & Miranda, 1996; Lamb & Jones, 1998). Finally, research on matching by ethnicity usually involves broad categories, such as patient and therapist who are both Asian American. However, when patients prefer a therapist from their own ethnic group, matching them with a therapist from a broadly similar group may not suffice. A Korean American patient, for instance, may prefer a Korean American therapist, but if such a therapist is not available, that patient may not prefer a Chinese American therapist over a therapist of any other background (Karlsson, 2005).

Culturally Sanctioned Placebo Effects

As we saw in Chapter 1, throughout time and across cultures, people in the role of healer have used different methods to treat abnormality. For some of the problems treated by healers—in the past and present—the placebo effect may be a key element of successful treatment. For instance, among the Shona people of Africa, those who have psychological problems often visit a *n'anga* (healer), who may recommend herbal remedies or steam baths or may throw bones to determine the source of a person's "bewitchment." Once the source is determined, the ill person's family is told how to mend community tensions that may have been caused by a family member's transgressing in some way (Linde, 2002). Westerners might consider the *n'anga's* treatments, if effective, to work because of the placebo effect and the common factors that arise from any treatment (even a placebo): hope, support, and a framework for understanding the problem and its resolution.

But members of nonindustrialized societies are not the only ones who are susceptible to such cultural forces. In Western cultures over the past two decades, people diagnosed with depression who are enrolled in studies to evaluate various medications have responded progressively more strongly to placebos (Walsh et al., 2002). Over that same two decades, pharmaceutical companies have increasingly advertised their medications directly to potential consumers, informing them about the possible benefits of the drugs. It is possible that the participants in these studies became more likely to believe that medication will be helpful than were participants 30 years ago, before direct advertising to consumers.

FEEDBACK LOOPS IN ACTION: The Placebo Effect

Successful treatments (including placebos) that target one type of factor in turn affect other types of factors; for example, medication (which targets neurological factors) affects symptoms related to psychological and social factors. Moreover, all types of treatment make use of a social factor—cultural norms about what kinds of interventions are appropriate, be they healer-induced possession trance or cognitive restructuring. In turn, these norms about appropriate treatment promote the patient's beliefs and expectations (psychological factor) regarding how effective the treatments are. Such beliefs and expectations then influence neurological and social factors, as well as other psychological factors. For example, a meta-analysis of studies on antidepressant treatments found that about 75–80% of the antidepressant's positive effects could be attributed to a placebo response, leaving at most only about 25% of the response due to the active ingredients of the medications. Thus, expectations that symptoms will improve may account for the lion's share of the positive response to an antidepressant (Kirsch & Lynn, 1999; Kirsch et al., 2002; Kirsch & Sapirstein, 1999; Walach & Maidhof, 1999). Indeed, more than half of studies of antidepressants that were funded by drug companies (which, if anything, may have biased the results towards supporting the effects of medication) found that a placebo was just as effective as the medication (Kirsch et al., 2002; Kirsch, Scoboria, & Moore, 2002; Moncrieff & Kirsch, 2005). In studies in which the placebo was designed to mimic the side effects of an antidepressant, the effects of the medication and the placebo were even more similar (Greenberg & Fisher, 1989).

These results do not necessarily show that placebos and actual antidepressant drugs have the same effects. Depressed people who responded well to SSRI medication, for instance, had a different pattern of brain activity than did patients who responded successfully to a placebo (Leuchter et al., 2002). Again, a patient's personal beliefs (psychological factor) about the effects of medication affect what happens in the brain, and these factors both affect, and are affected by, social factors.

Do the results regarding the placebo effect and antidepressants imply that depressed people should throw away their medication because they don't need it to attain the benefit? No! *Not taking any medication is not the same as taking a placebo medication.* There is something about the act of taking the medication that engages parts of the mind and brain to reduce depressive symptoms; without the placebo, these parts of the brain do not become active. There can't be a placebo effect without a placebo. So, if an antidepressant works for a patient, not taking it isn't at all the same as taking a placebo. (However, other nonmedical treatments may also be helpful for depression; we will discuss such treatments for that disorder in Chapter 6.)

What about Carlos and your hypotheses about loss and depression? As in the discovery of PANDAS, your observations about Carlos led you to identify questions about the etiology of his depression and about possible treatments. If you were interested in researching these matters, the particular design and procedure of your study would depend, in part, on the specific question you want to ask and hypothesis you want to test. You would use the scientific method to collect data (after obtaining approval from an IRB) and refine your hypothesis or formulate a theory.

If you wanted to test the efficacy of your grief box therapy, you would again use the scientific method, perhaps creating a treatment manual and organizing a RCT (in accordance with the guidelines for experimental treatments and with IRB approval). You might have four treatment groups: grief box only, encouraging social interactions only, grief box plus social interactions, and CBT (which serves as a nonexperimental comparison treatment). In this way, you could determine the relative effects of each component of your therapy, alone and in combination, and see how they fare against an established treatment. Depending on your results, you might refine your therapy.

Key Concepts and Facts About Researching Treatment

- When studying biomedical treatments, researchers should try to determine the extent to which a placebo effect—rather than a true drug effect—influences the results. Researchers should also take attrition rates into account when examining the effects of a treatment.
- Many of the challenges that arise in studying biomedical treatments, such as placebo effects and attrition, also arise when studying psychological treatments. A treatment may be effective because of common factors, as well as because of specific factors unique to that treatment. Control groups and analogue studies can allow researchers to examine specific factors and to rule out possible effects of some confounding factors. In general, research has demonstrated that therapy is more helpful than no treatment. Although the Dodo bird verdict found no one form of therapy superior *overall*, some specific therapies are better for some particular disorders.
- Randomized clinical trials (RCTs) are designed to investigate the efficacy of specific factors or treatments. RCTs typically involve manual-based treatment; some RCTs may have limited generalizability because of their exclusion criteria, homogenous samples, and other factors. Results of well-designed and well-conducted studies may indicate whether a particular treatment is empirically supported for a specific disorder. The results of research generally suggest a dose-response relationship. The code of ethics for psychologists includes specific guidelines for research on experimental treatments.
- Research on treatments that target social factors reveals that matching patients and therapists by ethnicity, gender, or age does not systematically alter the effectiveness of therapy. For patients with a strong preference, however, matching may lead to a better outcome. Cultural forces influence whether a treatment (including placebo) is effective.
- Any successful treatment, whatever type of neuropsychosocial factor it targets, also affects the other factors through feedback loops, inducing positive change. This is also true of changes that arise because of the placebo effect.

SUMMING UP

Summary of Using the Scientific Method to Understand Abnormality

Researchers use the scientific method to understand and study psychopathology. In doing so, they observe relevant phenomena, identify a question to be answered, develop a hypothesis that might answer the question, collect new observations to test the hypothesis, draw on the evidence to formulate a theory, and test the theory.

When conducting experiments, researchers systematically manipulate one or more independent variables and observe possible changes in one or more dependent variables. Researchers evaluate the possible contribution of confounds by using control groups or control conditions. To minimize unintentional bias, they randomly assign participants to groups. Experiments should have both inter-

nal and external validity. Researchers may use a quasi-experimental design when random assignment is not ethical, desirable, or possible.

Correlational research is used when independent variables cannot or should not be manipulated. Such studies allow researchers to investigate the relationship between two variables, specifically, whether a change in one variable is associated with a change in the other. However, a correlation does not imply causation; it only indicates that the two variables are related. Statistical significance indicates that the obtained measurement is greater than would be expected to occur by chance alone. Longitudinal studies of psychopathology often use correlational data.

Case studies allow a clinician or researcher to examine one individual in detail. Single-participant experiments (often using an ABAB design) provide information about how one variable affects another. However, the results of case studies may not general-

ize to other people. Meta-analysis allows researchers to aggregate the results of a number of studies that address the same question in order to determine the relations among certain variables.

Thinking like a researcher

Dr. Xavier studies compulsive gambling; she believes that people who begin gambling compulsively in their teens and early 20s have a different type of problem than those who begin gambling compulsively in their 40s or later. Based on what you have read about research methods, how would you state her question? What type of research design would you suggest she use (experimental, quasi-experimental, or correlational) and why? What might be some confounding variables for which she should try to control? How would Dr. Xavier go about ascertaining whether the study's results were statistically significant? What types of information would you want to

know before generalizing from her results to other people with compulsive gambling?

Summary of Research Challenges to Understanding Abnormality

Many studies that focus on neurological factors are correlational and so do not reveal how neurological factors may give rise to psychological disorders. Neuroimaging studies may indicate differences in brain structure or function between those with a psychological disorder and those without a disorder. However, it is not always clear how such differences contribute to a disorder.

Self-reports of patients or reports by others may be biased in what is paid attention to, remembered, or reported. In addition, participants may respond differently to questions that are asked during an interview and those that are presented on a questionnaire. Researchers must take care in phrasing questions in order to minimize misinterpretation and various types of biases.

Challenges in studying social factors can also create challenges for studying other types of factors. Such challenges include experimenter-influenced biases, such as experimenter expectancy effects (which can be reduced with a double-blind design) and reactivity. A major challenge for cross-cultural research on psychopathology is the difficulty of translating words or concepts across cultures.

Thinking like a researcher

Suppose that you are investigating pyromania—the intense urge to start fires. Your participants come from two groups: those who've been arrested for arson, and those who have interacted in a chat room for people with urges to start fires. To collect your data, you could either have participants complete an anonymous survey online or arrange to interview them over the phone. Discuss biases that might uniquely affect each method and biases that might affect both. How could you try to minimize these biases? Suppose you had some participants who agreed to have images taken of their brains while they imagined lighting fires: How might you, as a researcher, use the neuroimaging information?

Summary of Researching Treatment

When studying biomedical treatments, researchers should try to determine the extent to which a placebo effect—rather than a true drug effect—influences the results. Many of the challenges that arise in studying biomed-

ical treatments, such as placebo effects and attrition, also arise when studying psychological treatments. A treatment may be effective because of common factors, as well as because of specific factors that are unique to that treatment. In general, research has demonstrated that therapy is more helpful than no treatment. Although the Dodo bird verdict found no one form of therapy superior *overall*, some specific therapies are better for some particular disorders.

Randomized clinical trials (RCTs) are designed to investigate the efficacy of specific factors or treatments. RCTs typically involve manual-based treatment; some RCTs may have limited generalizability because of their exclusion criteria, homogenous samples, and other factors. Results of well-designed and well-conducted studies may indicate whether a particular treatment is empirically supported for a specific disorder. The results of research generally suggest a dose-response relationship.

Research on treatments that target social factors reveals that matching patients and therapists by ethnicity, gender, or age does not systematically alter the effectiveness of therapy. For patients with a strong preference, however, matching may lead to a better outcome. Any successful treatment, whatever type of neuropsychosocial factor it targets, also affects the other factors through feedback loops, inducing positive change. This is also true of change that arises because of the placebo effect.

Thinking like a researcher

Based on a survey, County Community College has found that 23% of their first-year students have anxiety or depression severe enough to meet the DSM-IV-TR criteria. The college would like to institute a treatment program for these students. In fact, the staff at the counseling center plans to conduct a research study and offer several different types of treatment: medication (if appropriate), CBT with an individual therapist, and CBT in group therapy. Students can sign up for whichever type of treatment they prefer and can even receive more than one type of treatment. The results will be recorded and used to guide how treatment is provided in the future. Is this study a randomized clinical trial—why or why not? What are some potential problems with the research design of this study? To learn whether each of the treatments is helpful to students, what questions should be asked of the students before and after the study?

Mood Disorders and Suicide

Kay Redfield Jamison, a psychologist who studies mood disorders, is uniquely qualified to report and reflect on such disorders. Not only has she made mood disorders her area of professional expertise, but she has also lived with such a disorder. In her memoir, *An Unquiet Mind* (1995), Jamison recounts her experiences. The youngest of three children in a military family, she and her siblings attended four different elementary schools—some in foreign countries—by the time she was in 5th grade. She describes her father, a meteorologist and Air Force officer, as expansive, with infectious good moods, and impulsive, often giving the children gifts. It was “like having Mary Poppins for a father” (Jamison, 1995, p. 17). However, he also suffered periods when he was immobilized by depression, and he generally had trouble regulating his emotions.

As we’ll see in this chapter, Jamison herself developed difficulties regulating her emotions. She recounts that when she was a senior in high school, her mood became so dark that her thinking

... was torturous. I would read the same passage over and over again only to realize that I had no memory at all for what I had just read. Each book or poem I picked up was the same way. Incomprehensible . . . I could not begin to follow the material presented in my classes. . . . It was very frightening . . . [my mind] no longer found anything interesting or enjoyable or worthwhile. It was incapable of concentrated thought and turned time and time again to the subject of death: I was going to die, what difference did anything make? Life’s run was only a short and meaningless one, why live? I was totally exhausted and could scarcely pull myself out of bed in the mornings. . . . I wore the same clothes over and over again, as it was otherwise too much of an effort to make a decision about what to put on. I dreaded having to talk with people, avoided my friends whenever possible, and sat in the school library in the early mornings and late afternoons, virtually inert, with a dead heart and a brain as cold as clay.

(Jamison, 1995, pp. 37–38)

In this passage, Jamison describes problems arising from her *mood*, a persistent emotion lurking in the background, regardless of what is occurring. The category of psychological disorders called **mood disorders** encompasses prolonged and marked disturbances in mood that affect how people feel, what they believe and expect, how they think and talk, and how they interact with others. In any particular year, about 8% of Americans experience a mood disorder (Substance Abuse and Mental Health Services Administration [SAMHSA], 2008). Mood disorders are among the leading causes of disability worldwide (World Health Organization [WHO], 2008).

Mood disorders

Psychological disorders characterized by prolonged and marked disturbances in mood that affect how people feel, what they believe and expect, how they think and talk, and how they interact with others.

Psychologist Kay Redfield Jamison described being depressed: “My mind would . . . be drenched in awful sounds and images of decay and dying: dead bodies on the beach, charred remains of animals, toe-tagged corpses in morgues. During these agitated periods I became exceedingly restless, angry, and irritable, and the only way I could dilute the agitation was to run along the beach or pace back and forth across my room like a polar bear at the zoo” (1995, p. 45).

Table 6.1 ▶ Four Types of Mood Disorder Episodes

- A *major depressive episode* involves symptoms of depression.
- A *manic episode* involves elated, irritable, or *euphoric* mood (mood that is extremely positive and may not necessarily be appropriate to the situation).
- A *hypomanic episode* involves elated, irritable, or euphoric mood that is less distressing or severe than mania and is different than the individual’s non-depressed state. That is, how a person behaves during a hypomanic episode is different from his or her usual state.
- A *mixed episode* involves symptoms of both a major depressive episode and a manic episode.

Major depressive episode (MDE)

A mood episode characterized by severe depression that lasts for at least 2 weeks.

Anhedonia

A difficulty or inability to experience pleasure.

DSM-IV-TR distinguishes between two categories of mood disorders: depressive disorders and bipolar disorders. *Depressive disorders* are mood disorders in which someone’s mood is consistently low; in contrast, *bipolar disorders* are mood disorders in which a person’s mood is sometimes decidedly upbeat, perhaps to the point of being manic, and sometimes may be low. Note that the mood disturbances that are part of depressive disorders and bipolar disorders are not the normal ups and downs that we all experience; they are more intense and longer lasting than just feeling “blue” or “happy.”

If such mood patterns are caused by substance abuse or a medical condition, a mental health clinician would not diagnose a mood disorder as the primary problem. Similarly, as with all clinical disorders, in order to be classified as a disorder, the symptoms of the mood disorder must cause significant distress, impair daily life, or put a person at risk of harm. The significant distress and suffering, along with a pervasive hopelessness that can arise with depression, sometimes lead people to contemplate or attempt suicide.

Using the DSM system to categorize mood disorders, a clinician must “build” a diagnosis based on a person’s current and past history of disturbed moods. In DSM-IV-TR, each type of *episode* of a mood disorder is a “building block,” with a diagnosis based on the presence or absence of different types of blocks. DSM-IV-TR defines four types of episodes: *major depressive episode*, *manic episode*, *hypomanic episode*, and *mixed episode* (see Table 6.1). Should a patient experience additional types of mood episodes over time, his or her diagnosis may change.

Let’s first examine depressive disorders—what they are and their causes and treatments—and then consider bipolar disorders. Once we know more about mood disorders, we’ll examine what is known about suicide and its prevention.

Depressive Disorders

Most people who read Jamison’s description of her senior year in high school would think that she was depressed during that time. But what, exactly, does it mean to say someone is *depressed*? The diagnoses of depressive disorders are based on the building block referred to as a *major depressive episode*; people whose symptoms have met the criteria for a major depressive episode (see Table 6.2) are diagnosed with *major depressive disorder*.

The Building Block of Depressive Disorders: Major Depressive Episode

A clinician who uses the DSM-IV-TR system to categorize mood disorders builds a diagnosis based on a person’s current and past history of episodes of disturbed moods. For depressive disorders, there is only one building block: **major depressive episode (MDE)**, which is characterized by severe depression that lasts for at least 2 weeks. MDE is not itself a diagnosis, but a building block toward a diagnosis (as we shall see later in this chapter, the diagnosis for other disorders typically requires several building blocks). Mood (which is a type of *affect*) is not the only symptom of a major depressive episode. Behavior and cognition are also affected by depression. These three spheres of functioning are sometimes referred to as the *ABCs*—affect, behavior, and cognition (but should not be confused with the ABCs of behavior therapy—antecedent, behavior, consequence).

Affect, the Mood Symptoms of Depression

During a major depressive episode, a person can feel unremitting sadness, hopelessness, or numbness. Some people also suffer from a loss of pleasure, referred to as **anhedonia**, a state in which activities and intellectual pursuits that were once enjoyable no longer are, or at least are not nearly as enjoyable as they had been. Someone who liked to go

Table 6.2 ▶ DSM-IV-TR Diagnostic Criteria for Major Depressive Episode

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood (symptom 1, below) or (2) loss of interest or pleasure (symptom 2, below).

Note: Do not include symptoms that are clearly due to a general medical condition or mood-incongruent [i.e., not consistent with the mood] delusions or hallucinations.

- (1) Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful). Note: In children and adolescents, can be irritable mood.
- (2) Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others).
- (3) Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month) or decrease or increase in appetite nearly every day. Note: In children, consider failure to make expected weight gains.
- (4) Insomnia or hypersomnia nearly every day.
- (5) Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
- (6) Fatigue or loss of energy nearly every day.
- (7) Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
- (8) Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
- (9) Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation [i.e., thoughts about suicide] without a specific plan, or a suicide attempt or a specific plan for committing suicide.

B. The symptoms do not meet criteria for a mixed episode [discussed later in this chapter].

C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

D. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).

E. The symptoms are not better accounted for by bereavement, i.e., after the loss of a loved one. The symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

Source: Reprinted with permission from the DSM-IV-TR Casebook: A Learning Companion to the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision, (Copyright 2002) American Psychiatric Association.

Major depressive episode includes affective/mood (green), behavioral/vegetative (orange), and cognitive (blue) symptoms.

to the movies, for instance, may no longer find it so interesting or fun and may feel that it is not worth the effort. Anhedonia can thus lead to social withdrawal. Other mood-related symptoms of depression include weepiness—crying at the drop of a hat or for no apparent reason—and decreased sexual interest or desire.

Behavioral and Physical Symptoms of Depression

People who are depressed make more negative comments, make less eye contact, are less responsive, speak more softly, and speak in shorter sentences than people who are not depressed (Gotlib & Robinson, 1982; Segrin & Abramson, 1994). Depression is also evident behaviorally in one of two ways: *psychomotor agitation* or *psychomotor retardation*. **Psychomotor agitation** is an inability to sit still, evidenced by pacing, hand wringing, or rubbing or pulling the skin, clothes, or other objects. In contrast, **psychomotor retardation** is a slowing of motor functions indicated by slowed bodily movements and speech (in particular, longer pauses in answering) and lower volume, variety, or amount of speech.

These two psychomotor symptoms, along with changes in appetite, weight, and sleep, are classified as **vegetative signs** of depression. Sleep changes can involve

Psychomotor agitation

An inability to sit still, evidenced by pacing, hand wringing, or rubbing or pulling the skin, clothes or other objects.

Psychomotor retardation

A slowing of motor functions indicated by slowed bodily movements and speech and lower volume, variety, or amount of speech.

Vegetative signs (of depression)

Psychomotor symptoms as well as changes in appetite, weight, and sleep.

insomnia or, less commonly, **hypersomnia**, which is sleeping more hours each day than normal. In addition, people who are depressed may feel less energetic than usual or feel tired or fatigued even when they don't physically exert themselves. In fact, many people who are depressed had sleep disturbances up to a month before the depression began, which suggests that sleep irregularities may be a harbinger of a depressive episode (Perlis et al., 1997; Perlis, Smith, et al., 2006). Sleep irregularities in depressed people are particularly notable during the phase when dreams primarily take place, known as *rapid eye movement* sleep (REM sleep) (Rao et al., 2002); REM sleep is involved in processing emotional memories (Marano, 2003).

In order to meet the diagnostic criteria, the vegetative signs should be observable by others, not just reported as subjective experiences. For instance, if a new patient reported difficulty getting to sleep, poor appetite, and feeling agitated, the clinician would ask the patient for more details before determining that these were vegetative signs of depression: How long does it actually take the patient to get to sleep? Has the patient's weight changed? The clinician would also observe the patient for signs of psychomotor agitation, such as a leg constantly bobbing up and down or fingers tapping on the armrest.

Cognitive Symptoms of Depression

When in the grip of depression, people often feel worthless or guilt-ridden, may evaluate themselves negatively for no objective reason, and tend to ruminate over their past failings (which they may exaggerate). They may misinterpret ambiguous statements made by other people as evidence of their worthlessness. For instance, a depressed man, Tyrone, might hear a colleague's question "How are you?" as an indication that he is incompetent and infer that the colleague is asking the question because Tyrone's incompetence is so obvious. Depressed patients can also feel unwarranted responsibility for negative events, to the point of having delusions that revolve around a strong sense of guilt, deserved punishment, worthlessness, or personal responsibility for problems in the world. They blame themselves for their depression and for the fact that they cannot function well. During a depressive episode, people may also report difficulty thinking, remembering, concentrating, and making decisions, as author William Styron describes, in Case 6.1. To others, the depressed person may appear distracted. Note, however, that depression is *heterogeneous*, which means that people with depression experience these symptoms in different combinations. No single set of symptoms is shared by all people with depression (Hasler et al., 2004).

Hypersomnia

Sleeping more hours each day than normal.

Prodrome

Early symptoms of a disorder.

Premorbid

Referring to the period of time prior to a patient's illness.

Major depressive disorder (MDD)

The mood disorder marked by five or more symptoms of an MDE lasting more than 2 weeks.

Age cohort

A group of people born in a particular range of years.

CASE 6.1 ► FROM THE INSIDE: Major Depressive Episode

Another experience of depression was captured by the writer William Styron in his memoir, *Darkness Visible*.

In depression this faith in deliverance, in ultimate restoration, is absent. The pain is unrelenting, and what makes the condition intolerable is the foreknowledge that no remedy will come—not in a day, an hour, a month, or a minute. If there is mild relief, one knows that it is only temporary; more pain will follow. It is hopelessness even more than pain that crushes the soul. So the decision-making of daily life involves not, as in normal affairs, shifting from one annoying situation to another less annoying—or from discomfort to relative comfort, or from boredom to activity—but moving from pain to pain. One does not abandon, even briefly, one's bed of nails, but is attached to it wherever one goes.

(Styron, 1990, p. 62)

The symptoms of MDE develop over days and weeks. The **prodrome** is the early symptoms of the disorder, and the prodrome of an MDE may include anxiety or mild depressive symptoms that last for weeks to months before fully

emerging as a major depressive episode. An untreated MDE typically lasts approximately 4 months or longer (American Psychiatric Association, 2000). The more severe the depression, the longer the episode is likely to last (Melartin et al., 2004). About two thirds of people who have an MDE eventually recover from the episode completely and return to their previous level of functioning—referred to as the **premorbid** level of functioning. About 20–30% of people who have an MDE find that their symptoms lessen over time to the point where they no longer meet the criteria for an MDE but don't completely resolve and may persist for years. One suggestion for DSM-V addresses the fact that some symptoms—but not enough for a diagnosis—persist for months or years: Evaluate depressive symptoms on two continua—how severe and how chronic the symptoms are—rather than with the current categorical system of whether or not symptoms meet the criteria (Klein, 2008).

What distinguishes depression from simply “having the blues”? One distinguishing feature is the number of symptoms. People who are sad or blue generally have fewer than five of the symptoms listed in the DSM-IV-TR diagnostic criteria for a major depressive episode (see Table 6.2). In addition, someone who is truly depressed has severe symptoms for a relatively long period of time and is unable to function effectively at home, school, or work. Moreover, pervasive hopelessness and loss of pleasure are usually absent in normal sadness.

Major Depressive Disorder

According to DSM-IV-TR, once someone's symptoms meet the criteria for a major depressive episode, he or she is diagnosed as having **major depressive disorder (MDD)**—five or more symptoms of an MDE lasting more than 2 weeks. Thus, once Kay Jamison had her first major depressive episode, she had the diagnosis of MDD, *single episode*. Unfortunately, more than half of those who have had a single depressive episode go on to have at least one additional episode, noted in DSM-IV-TR as MDD, *recurrent depression*. Some people have increasingly frequent episodes over time, others have clusters of episodes, and still others have isolated depressive episodes followed by several years without symptoms (American Psychiatric Association, 2000; McGrath et al., 2006). Research suggests that periods of remission last longer earlier in life. That is, as people with recurrent MDD grow older, they are free of depression for increasingly shorter periods (American Psychiatric Association, 2000).

MDD is very common in the United States: Up to 20% of Americans will experience it sometime in their lives (American Psychiatric Association, 2000; Kessler et al., 2003). Unfortunately, the documented rate of depression in the United States is increasing (Lewinsohn et al., 1993), perhaps because of increased stressors in modern life or decreased social support; in addition, at least part of this increase may simply reflect higher reporting rates. By 2020, depression will probably be ranked second among disabling diseases in the United States (right after heart disease; Schrof & Schultz, 1999); it is currently associated with more than \$30 billion dollars of lost productivity among U.S. workers annually (Stewart et al., 2003).

Evidence also suggests that the risk of developing depression is increasing for each **age cohort**, a group of people born in a particular range of years. The risk of developing depression is higher among people born more recently than those born previously. In addition, if someone born more recently does develop depression, that individual probably will first experience it earlier in life than someone in an older cohort (American Psychiatric Association, 2000). Table 6.3 provides more facts about MDD.

Tim Sloan/AFP/Getty Images

Normal bereavement has characteristics that are similar to symptoms of a major depressive episode: sad thoughts and feelings, problems in concentrating, and changes in appetite and sleep. However, bereaved people are not generally overcome with feelings of hopelessness or anhedonia.

Spencer Platt/Getty Images

Major depressive disorder leads to lowered productivity at work—both from missing days at work and from *presenteeism*, being present at work but less productive than normal (Adler et al., 2006; Druss, Schlesinger, & Allen, 2001; Stewart et al., 2003). For people whose jobs require high levels of cognitive effort, even mild memory or attentional difficulties may disrupt their ability to function adequately at work.

Table 6.3 ▶ Major Depressive Disorder Facts at a Glance

Prevalence

- Around 10–25% of women and 5–12% of men will develop MDD over their lifetimes. Before puberty, however, boys and girls develop MDD in equal numbers (Kessler et al., 2003).
- People with different ethnic backgrounds, education levels, incomes, and marital statuses are generally afflicted equally over their lives (American Psychiatric Association, 2000; Kessler et al., 2003; Weissman et al., 1991).

Comorbidity

- Most people with MDD also have an additional psychological disorder (Rush et al., 2005), such as an anxiety disorder (Barbee, 1998; Kessler et al., 2003) or substance abuse (Rush et al., 2005).

Onset

- MDD can begin at any age, with the average age of onset in the mid-20s, although people are developing MDD at increasingly younger ages.

Course

- Among individuals who have had a single MDE, approximately 50–65% will go on to have a second episode (Angst et al., 1999; American Psychiatric Association, 2000; Solomon et al., 2000).
- Those who have had two episodes have a 70% chance of having a third, and those who have had three episodes have a 90% chance of having a fourth.

Gender Differences

- As noted above, women are almost twice as likely as men to develop MDD (American Psychiatric Association, 2000; Kessler, 2003).
- Some women report that depressive symptoms become more severe premenstrually.

Source: Unless otherwise noted above, the source for information is American Psychiatric Association, 2000.

Because of the high comorbidity between depression and anxiety disorders (about 50%), researchers propose that the two types of disorders have a common cause, presently unknown. We will further discuss reasons for the high comorbidity between these two types of disorders when we consider anxiety disorders in Chapter 7.

Specifiers

The DSM-IV-TR criteria list includes *specifiers*—specific sets of symptoms that occur together or in particular patterns. Specifiers help clinicians and researchers identify or note variants of a disorder, which is important because each variant may respond best to a particular treatment or have a particular prognosis. For instance, depression with *melancholic features* includes complete anhedonia—the patient doesn’t feel any better after positive events. When a patient experiences depression with melancholic features, the symptoms usually fluctuate during the day—he or she typically wakes early in the morning, feels worse in the morning, and loses his or her appetite. In contrast, *atypical depression* is characterized by depressed mood that brightens when good things happen, along with at least two of the following: hypersomnia, increased weight gain, heavy feelings in arms or legs, and persistent sensitivity to perceived rejection by others (American Psychiatric Association, 2000). Atypical depression is likely to respond to different medications than is depression with melancholic features (Rosenbaum et al., 2005).

Symptoms of depression may also include *catatonic features*, which are specific motor symptoms—rigid muscles that hold odd postures for long periods of time, or a physical restlessness. Although not common, depression can occur with *psychotic*

features—hallucinations (e.g., in which a patient can feel that his or her body is decaying) or delusions (e.g., in which the patient believes that he or she is evil and living in hell).

Symptoms may also form a pattern over time. In contrast to recurrent depression, in which symptoms of an MDE disappear and then reemerge at a later time, *chronic depression* is the pattern in which the symptoms meet the criteria for an MDE continuously for over 2 years. In some cases, such as that of Marie Osmond in Case 6.2, depression emerges within 4 weeks of giving birth, designated as *postpartum onset*. However, the DSM-IV-TR cutoff of 4 weeks for postpartum onset may be too restrictive; 6 months to 1 year after giving birth may be a more useful diagnostic cutoff (Wisner et al., 2004), although some women develop symptoms as soon as 5 days after delivery (Adewuya, 2006) or even before the birth (Evans et al., 2001). Those most at risk for postpartum depression are women who have had recurrent depression before giving birth (Forty et al., 2006).

Laura Dwight/Photo Edit

Although postpartum depression can arise after giving birth, for many women, “postpartum” depression may actually begin during pregnancy, particularly the latter half, and persist after the birth (Evans et al., 2001).

CASE 6.2 ► FROM THE INSIDE: Postpartum Onset of Depression

After the birth of her seventh child, Marie Osmond developed postpartum depression:

I’m collapsed in a pile of shoes on my closet floor. . . . I sit with my knees pulled up to my chest. I barely move. It’s not that I want to be still. I am numb. I can tell I’m crying, but it’s not like tears I’ve shed before. My eyes feel as though they have moved deep into the back of my head. There is only hollow space in front of them. Dark, hollow space. I am as empty as the clothing hanging above me. Despite my outward appearance, I feel like a lifeless form.

I can hear the breathing of my sleeping newborn son in his bassinet next to the bed. My ten-year-old daughter, Rachael, opens the bedroom door and whispers, “Mom?” into the room, trying not to wake the baby. Not seeing me, she leaves. She doesn’t even consider looking in the closet on the floor. Her mother would never be there. She’s right. This person sitting on the closet floor is nothing like her mother. I can’t believe I’m here myself. I’m convinced that I’m losing my mind. This is not me.

I feel like I’m playing hide-and-seek from my own life, except that I just want to hide and never be found. I want to escape my body. I don’t recognize it anymore. I have lost any resemblance to my former self. I can’t laugh, enjoy food, sleep, concentrate on work, or even carry on a conversation. I don’t know how to go on feeling like this: the emptiness, the endless loneliness. Who am I? I can’t go on.

(Osmond, Wilkie, & Moore, 2001)

Sometimes recurrent depression follows a seasonal pattern, occurring at a particular time of year. Referred to as **seasonal affective disorder (SAD)**, this disorder manifests itself in two patterns:

- *Winter depression* is characterized by recurrent depressive episodes, hypersomnia, increased appetite (particularly for carbohydrates), weight gain, and irritability. These symptoms begin in autumn and continue through the winter months. The symptoms either disappear or are much less severe in the summer. Surveys find that approximately 4–6% of the general population experiences a winter depression, and the average age of onset is 23 years. The disorder is four times more common in women than in men (American Psychiatric Association, 2000). Winter depression often can be treated effectively with **phototherapy** (also called *light-box therapy*), in which full-spectrum lights are used as a treatment (Golden et al., 2005).
- *Summer depression*, which is less common, tends to appear in late spring. Symptoms often include poor appetite and weight loss, less sleep, and psychomotor changes (American Psychiatric Association, 2000). Treatment for summer depression usually includes antidepressant medication.

Seasonal affective disorder (SAD)

Recurrent depression that follows a seasonal pattern.

Phototherapy

Treatment for depression that uses full-spectrum lights; also called *light-box therapy*.

Pascal Goetgheluck/Photo Researchers

Phototherapy can be helpful to people who have winter depression. Typically, a person using phototherapy sits near special lights for an average of 30 minutes per day.

Depression in Children and Adolescents

In a given 6-month period, 1–3% of elementary-school children and 5–8% of teenagers are depressed (Garber & Horowitz, 2002; Lewinsohn & Essau, 2002). Moreover, some clinicians and researchers are reporting depression among preschool children, evidenced by avoidance, decreased enthusiasm and increased anhedonia (Luby et al., 2006). Younger children who are depressed are not generally considered to be at high risk to develop depression in adulthood (Harrington et al., 1990; Weissman, Wolk, Wickramaratne, et al., 1999). However, those who first get depressed as teenagers are considered to be at high risk for developing depression in adulthood (Lewinsohn, Rohde, et al., 1999; Weissman et al., 2006; Weissman, Wolk, et al., 1999). Teenage depression has far-reaching effects: Depressed teens are more likely than their nondepressed peers to drop out of school or to have an unplanned pregnancy (Waslick, Kandel, & Kakouros, 2002).

Dysthymic Disorder

Dysthymic disorder differs from major depressive disorder in that it involves fewer of the symptoms of a major depressive episode, but they persist for a longer period of time. Specifically, dysthymic disorder is characterized by depressed mood and as few as two other depressive symptoms that last for at least 2 years and that do not recede for longer than 2 months at any time during that period (see Table 6.4).

Because symptoms are chronic, people with dysthymic disorder often incorporate the symptoms into their enduring self-assessment, seeing themselves as incompetent or uninteresting. Whereas people with MDD see their symptoms as happening *to* them, people with dysthymic disorder view their symptoms as an integral part of themselves (“This is just how I am”), like Mr. A, in Case 6.3, below. If an individual diagnosed with dysthymic disorder develops an MDE, he or she is considered to have **double depression**. In that case, both MDD and dysthymic disorder are diagnosed. Individuals who have had double depression are likely to have more than one MDE. Double depression may require longer treatment than dysthymic disorder or MDD (Dunner, 2001).

CASE 6.3 ► FROM THE OUTSIDE: Dysthymic Disorder

Mr. A, a 28-year-old, single accountant, sought consultation because “I feel I am going nowhere with my life.” Problems at work included a recent critical job review because of low productivity, conflicts with his boss, and poor management skills. His fiancée recently postponed their wedding because she has doubts about their relationship, especially his remoteness, critical comments, and lack of interest in sex.

Describing himself as a pessimist who has difficulty experiencing pleasure or happiness, Mr. A has long felt a sense of hopelessness—of life not being worth living. His mother was hospitalized with postpartum depression after the birth of his younger sister; his father had a drinking problem. His high school classmates found him gloomy and “not fun.”

Although not troubled by thoughts of suicide nor significant vegetative signs of depression, Mr. A. does have months when his concentration is impaired, his energy level is lowered, and his interest in sex wanes. At such times, he withdraws from other people (although he always goes to work), staying in bed on weekends.

(Adapted from Frances & Ross, 1996, pp. 123–124)

Dysthymic disorder

A depressive disorder that involves fewer of the symptoms of a major depressive episode, but the symptoms persist for a longer period of time.

Double depression

Having both major depressive disorder and dysthymic disorder.

How would a clinician determine whether Mr. A, or someone else, suffered from dysthymic disorder or MDD—what differentiates the two disorders? People with dysthymic disorder are less likely to experience the vegetative signs associated

Table 6.4 ▶ DSM-IV-TR Diagnostic Criteria for Dysthymic Disorder

A. Depressed mood for most of the day, for more days than not, as indicated either by subjective account or observation by others, for at least 2 years.

Note: In children and adolescents, mood can be irritable and duration must be at least 1 year.

B. Presence, while depressed, of two (or more) of the following:

- (1) poor appetite or overeating
- (2) insomnia or hypersomnia
- (3) low energy or fatigue
- (4) low self-esteem
- (5) poor concentration or difficulty making decisions
- (6) feelings of hopelessness

C. During the 2-year period (1 year for children or adolescents) of the disturbance, the person has never been without the symptoms in Criteria A and B for more than 2 months at a time.

D. No major depressive episode has been present during the first 2 years of the disturbance (1 year for children and adolescents); i.e., the disturbance is not better accounted for by chronic major depressive disorder, or major depressive disorder, in partial remission.

Note: There may have been a previous major depressive episode provided there was a full remission (no significant signs or symptoms for 2 months) before development of the dysthymic disorder. In addition, after the initial 2 years (1 year in children or adolescents) of dysthymic disorder, there may be superimposed episodes of major depressive disorder, in which case both diagnoses may be given when the criteria are met for a major depressive episode.

E. There has never been a manic episode, a mixed episode, or a hypomanic episode, and criteria have never been met for cyclothymic disorder [all discussed later in the chapter].

F. The disturbance does not occur exclusively during the course of a chronic psychotic disorder, such as schizophrenia or delusional disorder [all discussed in Chapter 12].

G. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).

H. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Source: Reprinted with permission from the DSM-IV-TR Casebook: A Learning Companion to the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision, (Copyright 2002) American Psychiatric Association.

with an MDE (psychomotor symptoms and changes in sleep, appetite, and weight; American Psychiatric Association, 2000). Other factors that can help a clinician distinguish between major depressive disorder and dysthymic disorder are age of onset (generally younger with dysthymic disorder), symptom duration (longer with dysthymic disorder), and number of symptoms (fewer with dysthymic disorder). See Table 6.5 for more facts about dysthymic disorder.

Understanding Depressive Disorders

How do depressive disorders arise? Why do some people, but not others, suffer from them? Like all psychological disorders, depressive disorders are best understood as arising from neurological, psychological, and social factors, and the feedback loops among them.

Neurological Factors

Neurological factors that contribute to depressive disorders can be classified into three categories: brain systems, neural communication, and genetics. Stress-related hormones—which underlie a specific kind of neural communication—are particularly important in understanding depressive disorders, and thus we consider them in a separate section below.

Table 6.5 ▶ Dysthymic Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none"> • In a given year, 3% of Americans have dysthymic disorder; 6% will have it over the course of their lives.
Comorbidity
<ul style="list-style-type: none"> • Among individuals with dysthymic disorder without a prior history of MDD, the risk of subsequently developing MDD is approximately 75% within 5 years of the onset of dysthymia. • People with dysthymic disorder may also develop a substance-related disorder.
Onset
<ul style="list-style-type: none"> • The onset of dysthymia tends to be earlier than that of MDD.
Course
<ul style="list-style-type: none"> • The spontaneous remission rate (that is, the rate at which the disorder gets better by itself, without any treatment) for people with dysthymic disorder is only 10% per year. • In one 10-year study, almost 75% of people with dysthymic disorder recovered within 5 years, but over 70% of the patients who recovered had a recurrence by the end of the study (Klein, Shankman, & Rose, 2006). • Each year, approximately 10% of individuals with dysthymic disorder will have their first MDE. • People whose dysthymic disorder precedes the onset of MDD, as occurs for 10–25% of people with MDD, are less likely to have a full recovery between episodes without treatment.
Gender Differences
<ul style="list-style-type: none"> • Boys and girls are equally likely to develop dysthymic disorder. • In adulthood, women are two to three times more likely than men to develop dysthymic disorder.

Brain Systems

Studies of depressed people have shown that they have unusually low activity in a part of the frontal lobe that has direct connections to the amygdala (which is involved in fear and other strong emotions) and to other brain areas involved in emotion (Kennedy et al., 1997). This finding hints that the depressed brain is not as able as the normal brain to regulate emotion. Moreover, this part of the frontal lobe has connections to the brain areas that produce the neurotransmitter substances dopamine, serotonin, and norepinephrine. Thus, this part of the frontal lobe may well be involved in regulating the amounts of such substances. This is important because these substances are involved in reward and emotion, which again hints that the brains of these people are not regulating emotion normally.

Researchers have refined this general observation and reported that one aspect of depression—lack of motivated behavior—is specifically related to reduced activity in the frontal (and parietal) lobes (Milak et al., 2005). In addition, these researchers report that depression does not simply reflect that the brain as a whole has become sluggish. Rather, they found that more severe depression is associated with *greater* activity in the emotion-related limbic system, which fits with the idea that emotions are not being effectively regulated. Moreover, these researchers found that some of the brain areas involved in attention (in particular, the thalamus) and in controlling movements (basal ganglia) are overactive in depressed people, which again suggests that the functions carried out by these brain areas are not being regulated normally.

Neural Communication

Researchers have long known that the symptoms of depression can be alleviated by medications that alter the activity of serotonin or norepinephrine (Arana & Rosenbaum, 2000). Indeed, when this fact was first discovered, some researchers

thought that the puzzle of depression was nearly solved. However, we now know that the story is not that simple—depression is not caused by too much or too little of a specific neurotransmitter. Instead, the disorder arises in part from complex interactions among numerous neurotransmitter substances, which depend on how much of each is released into the synapses, how long each substance lingers in the synapse, and how the substances interact with receptors in other areas of the brain that are involved in the symptoms of depression (Nemeroff, 1998).

One of the early attempts to explain depression in terms of a single neurotransmitter is called the *catecholamine hypothesis*, which posits that symptoms of depression arise when levels of norepinephrine fall too low (Schildkraut, 1965). Support for this hypothesis came from studies showing that people who are depressed have fewer by-products of norepinephrine in their urine and cerebrospinal fluid (Nemeroff, 1998). Perhaps surprisingly, however, autopsies of the brains of people who were depressed found that many of them had a *higher* than normal density of norepinephrine receptors (Meana, Barturen, & Garcia-Sevilla, 1992). At first glance, this last finding may seem at odds with the first finding—why would people who have *less* norepinephrine have *more* receptors that respond to that neurotransmitter? This apparent paradox is resolved by knowing that when the brain doesn't produce enough of a neurotransmitter, it often attempts to compensate by increasing the number of receptors that respond to it. An increase in the number of receptors allows a given amount of neurotransmitter to have a larger effect.

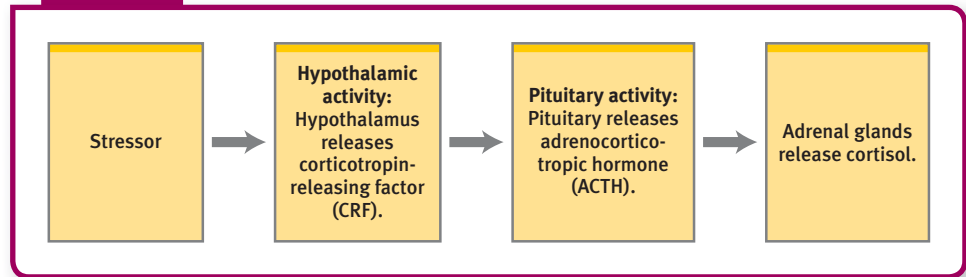

Further support for the catecholamine hypothesis came from the finding that depression can be treated by drugs that block norepinephrine reuptake (Brunello & Racagni, 1998; Schatzberg, 2000). These drugs keep more norepinephrine in the synapse for a longer period of time, which means that less additional norepinephrine needs to be produced to affect the receptors.

But the neurotransmitter norepinephrine and the catecholamine hypothesis cannot be the whole story. Additional studies have implicated the neurotransmitter serotonin in depression (Booij & Van der Does, 2007; Munafò et al., 2006). Some researchers hypothesize that serotonin affects depression through its influence on norepinephrine activity (Schildkraut, 1965). However, other researchers have shown that serotonin directly affects the amygdala (which plays an important role in emotional expression; LeDoux, 2000), the hypothalamus (which is involved in vegetative signs of depression; Swaab, 2003), and cortical brain areas involved in thinking and judgment (Smith & Kosslyn, 2006). Moreover, measurements of cerebrospinal fluid and autopsy studies have shown that depressed people have lower levels of serotonin than normal (Sullivan et al., 2006). And, just as was documented for norepinephrine, lower levels of serotonin are associated with greater numbers of certain serotonin receptors, and drugs that block the reuptake of serotonin relieve symptoms of depression (Arroll et al., 2005).

Dopamine also appears to play several roles in depression (Nutt, 2008); too little of it not only can undermine the effects of reward (and hence can lead to lack of pleasure), but also can produce psychomotor retardation (Clausius, Born & Grunz, 2009; Martin-Soelch, 2009; Stein, 2008). In short, depression involves not only norepinephrine, but also serotonin and dopamine—and perhaps other neurotransmitters as well.

Stress-Related Hormones

The chemical story doesn't end with neurotransmitters. Nemeroff (1998, 2008) formulated the *stress–diathesis model* of depression (which is to be distinguished from the general *diathesis–stress model*, discussed in Chapter 1). The stress–diathesis model of depression focuses specifically on the hypothalamic-pituitary-adrenal axis (HPA axis; discussed in Chapter 2) and the role of cortisol, a hormone that is secreted in larger amounts when an individual experiences stress (see Figure 6.1). According to the stress–diathesis model, people with depression have an excess of cortisol circulating in their blood, which makes their brains prone to overreacting when they experience stress. Moreover, this stress reaction, in turn, alters the serotonin and norepinephrine systems, which underlie at least some of the symptoms of depression. Antidepressants

Figure 6.1

6.1 ► The HPA Axis Stress activates the hypothalamus, which releases corticotropin-releasing factor (CRF), which in turn stimulates the pituitary gland to release adrenocorticotrophic hormone (ACTH), which then instructs the adrenal glands to release cortisol. According to the stress–diathesis model of depression, people who become depressed have high levels of cortisol, which lead to heightened reactivity to stress and increased serotonin levels.

and electroconvulsive therapy (ECT) can lower people’s cortisol levels in addition to decreasing their depressive symptoms (Deuschle et al., 2003; Werstiuk et al., 1996).

The stress–diathesis model of depression receives support from several sources (Nemeroff, 2008). For one, higher levels of cortisol are associated with decreases in the size of the hippocampus, which thereby impairs the ability to form new memories (of the sort that later can be voluntarily recalled)—which in turn may contribute to the decreased cognitive abilities that characterize depression. And, in fact, researchers have reported that parts of this brain structure are smaller in depressed people than in those who are not depressed (Neumeister, Charney, & Drevets, 2005; Neumeister et al., 2005), which suggests that stress affects the symptoms of depression in part by altering levels of cortisol, which in turn impairs the functioning of the hippocampus.

In addition, the role of stress in setting the stage for depression receives support from studies of newborn rats that were separated from their mothers for brief periods of time each day (Plotsky et al., 2005). In adulthood, these stressed rats not only had more HPA axis activity and higher levels of corticotropin-releasing factor (CRF) than their nonstressed counterparts, but they also had a greater density of CRF receptors in certain brain areas. Consistent with these findings, Paxil, an antidepressant medication that targets serotonin, seems to decrease activation of the HPA axis in rats that have been deprived of their mother’s presence (Plotsky, cited in Nemeroff, 1998). Moreover, when these rats are taken off Paxil, the increased activation resumes.

However, the stress–diathesis model describes only part of the neurological piece of depression. As noted earlier, dopamine also probably plays a role, and may do so independently of effects of stress. In addition, there’s an intriguing twist to the finding that HPA axis activity is related to depression: Whereas HPA axis activity increases in typical depression, it decreases in atypical depression (Kasckow, Baker, & Geraciotti, 2001). This finding suggests that the two forms of depression may arise in part from different neurological mechanisms.

Genetics

Twin studies show that when one twin of a monozygotic (identical) pair has MDD, the other twin has a risk of also developing the disorder that is four times higher than when the twins are dizygotic (fraternal; Bowman & Nurnberger, 1993; Kendler, Karkowski, & Prescott, 1999). Because monozygotic twins basically share all of their genes but dizygotic twins share only half of their genes, these results point to a role for genetics in the etiology of this disorder. One possibility is that genes influence how a person responds to stressful events (Costello et al., 2002; Kendler et al., 2005). If a person is sensitive to stressful events, the sensitivity could lead to increased HPA axis activation (Hasler et al., 2004), which in turn could contribute to depression.

However, genes are not destiny. The environment clearly plays an important role in whether a person will develop depression (Eley et al., 1998; Hasler et al., 2004; Rice, Harold, & Thaper, 2002; Wender et al., 1986). Even with identical twins, if one twin is depressed, this does not guarantee that the co-twin will also be depressed—in spite of their having basically the same genes. Whether a person gets depressed depends partly on his or her life experiences, including the presence of hardships and the extent of social support.

The environment plays a key role not only in whether the genes contribute to depression, but also in *how* the genes have their effects. In some cases, genetic factors may affect depression indirectly—by disrupting specific aspects of normal functioning that in turn trigger the disorder. For example, researchers have found that genetics may influence whether a person has disrupted sleep (Hasler et al., 2004; Modell et al., 2003), and adolescents who went on to develop the disorder (investigated in longitudinal studies) did have disrupted sleep.

Psychological Factors

Particular ways that people think about themselves and events, in concert with stressful or negative life experiences, can increase the risk of depression. In the following sections we consider psychological factors that can influence whether a person develops depression; these factors range from biases in attention to the effects of different ways of thinking to the results of learning.

Attentional Biases

Some people see a glass that is half full of water as being half empty. Similarly, some people focus their attention—consciously or unconsciously—on stimuli that are sad. People who are depressed are more likely to pay attention to sad and angry faces than to faces that display positive emotions (Gotlib, Kasch, et al., 2004; Gotlib, Krasnoperova, et al., 2004; Leyman et al., 2007); people who do not have a psychological disorder spend equal time looking at faces that express different emotions. This attentional bias has also been found for negative words and scenes, as well as for remembering depression-related—versus neutral—stimuli (Caseras et al., 2007; Gotlib, Kasch, et al., 2004; Matt, Vasquez, & Campbell, 1992; Mogg, Bradley, & Williams, 1995). Such an attentional bias may leave depressed people more sensitive to other people's sad moods and to negative feedback from others (or even a lack of positive feedback, as occurs when a person fails to smile when greeting you), compounding their depressive thoughts and feelings.

Dysfunctional Thoughts

As discussed in Chapter 2, Aaron Beck proposed that *cognitive distortions* are the root cause of many disorders. Beck (1967) has suggested that people with depression tend to have overly negative views about (1) the world, (2) the self, and (3) the future, referred to as the *negative triad of depression*. These distorted views can cause and maintain chronically depressed feelings and depression-related behaviors. For instance, a man who doesn't get the big raise he hoped for might respond with cognitive distortions that give rise to dysfunctional thoughts. He might think that he isn't "successful" because he didn't get the raise, and therefore that he must be worthless (notice the circular reasoning). This man is more likely to become depressed than he would be if he didn't have such dysfunctional thoughts.

Rumination

While experiencing negative emotions, some people reflect on these emotions; during such *ruminations*, they might say to themselves: "Why do bad things always happen to me?" or "Why did they say those hurtful things about me—is it something I did?" or "Should I have spoken more during the discussion?" (Nolen-Hoeksema & Morrow, 1991). Such ruminative thinking has been linked to depression (Just & Alloy, 1997; Nolen-Hoeksema, 2000; Nolen-Hoeksema & Morrow, 1991, 1993).

Studies have examined the relationship between depression and specific forms of rumination, such as *stress-reactive rumination*, which is ruminating about negative

implications of stressful life events. Researchers assess this type of rumination by asking participants to agree or disagree with statements about what they “generally do when feeling down, sad, or depressed.” Examples of such statements include:

- “Think about how the stressful event was all your fault”
- “Think about what the occurrence of the stressor means about you”
- “Think about how things like this always happen to you” (Robinson & Alloy, 2003).

To investigate the relationship between stress-reactive rumination and other cognitive vulnerabilities to depression (such as dysfunctional thoughts about oneself), researchers followed first-year college students who were not depressed at the time the study began (Robinson & Alloy, 2003). The investigators found that participants who *both* had a cognitive vulnerability for depression and engaged in stress-reactive rumination were, by senior year, more likely than participants who had only one or neither of these risk factors to (1) have experienced a depressive episode, (2) have had more depressive episodes, and (3) have had episodes of longer duration.

Attributional Style

When something bad happens, to what do you attribute the cause of the unfortunate turn of events? In general, people who consistently attribute negative events to their own qualities—called an *internal attributional style*—are more likely to become depressed. In one study, mothers-to-be who had an internal attributional style were more likely to be depressed 3 months after childbirth than were mothers-to-be who had an *external attributional style*—blaming negative events on qualities of others or on the environment (Peterson & Seligman, 1984). Similarly, college students who tended to blame themselves, rather than external factors for negative events, were more likely than those who did not to become depressed after receiving a bad grade (Metalsky et al., 1993).

Three particular aspects of attributions are related to depression: whether the attributions are *internal* or *external*, *stable* (enduring causes) or *unstable* (local, transient causes), and *global* (general, overall causes) or *specific* (particular, precise causes) (see Table 6.6). Individuals who tend to attribute negative events to internal, global, and stable factors were most likely to become depressed when negative events occurred. This *depressive attributional style*, along with dysfunctional thoughts, is associated with being vulnerable to depression (Abramson, Seligman, & Teasdale, 1978). People who think this way make negative predictions about the future, for example: “Even if I find another boyfriend, he’ll dump me too” (Abramson et al., 1999).

Charles Ommanney/Getty Images

Prison inmates who tended to attribute events to internal causes when they began to serve their sentences were more likely than other prisoners to become depressed after months of incarceration (Peterson & Seligman, 1984).

Internal (versus external), global (versus specific), and stable (versus unstable) attributions for negative events are associated with a cognitive vulnerability for depression (Abramson, Seligman, & Teasdale, 1978).

Table 6.6 ▶ Types of Attributions

Example attribution: “He broke up with me because . . .”				
	Internal (personal)		External (environmental)	
	Stable	Unstable	Stable	Unstable
Global	I am inherently unlovable.	I was going through a rough period then.	He is a jerk.	He acted impulsively.
Specific	I am not flexible enough about letting people take a couple of days to respond to e-mails that I send.	I wasn’t very flexible about his being late every time we arranged to get together last month.	He is incapable of being on time.	He didn’t like that I was so annoyed when he was consistently late last week.

In fact, people who consistently make global and stable attributions for negative events—whether to internal or external causes—are more likely to feel hopeless in the face of negative events and come to experience *hopelessness depression*, a form of depression in which hopelessness is a central element (Abramson, Metalsky, & Alloy, 1989). Such people expect (1) that undesirable outcomes will occur (and that desirable ones won't) and (2) that they are helpless to change the situation. However, it is the depressive attributional style *in conjunction with* negative events that elicits hopelessness (Hankin et al., 2004). That is, the attributional style alone won't necessarily lead to depression; it is only when an individual with this style experiences negative events that depression is likely to follow. For instance, hopelessness depression is more common among those who experienced emotional abuse during childhood (Gibb et al., 2001).

Learned Helplessness

Hopelessness depression is not always based on incorrect attributions. It can arise from situations in which, in fact, undesirable outcomes *do* occur and the individual *is* helpless to change the situation, such as the situation of children who experience physical abuse or neglect (Widom, Dumont, & Czaja, 2007). Such circumstances lead to *learned helplessness*, in which a person gives up trying to change or escape from a negative situation (Overmier & Seligman, 1967; see Chapter 2 for a more detailed discussion and technical definition). For example, people in abusive relationships might become depressed if they feel that they cannot escape the relationship and that no matter what they do, the situation will not improve.

Social Factors

Depression is also associated with a variety of social factors, including stressful life events (such as in personal relationships), social exclusion, and social interactions (which are affected by culture). These social factors can affect whether depression develops or persists.

Stressful Life Events

In approximately 70% of cases, an MDE occurs after a significant life stressor, such as getting fired from a job or losing an important relationship. Such events are particularly likely to contribute to a first or second depressive episode (American Psychiatric Association, 2000; Lewinsohn et al., 1999; Tennant, 2002).

It might seem obvious that negative life events can lead to depression, but separating possible confounding factors and trying to establish causality have challenged researchers. For instance, people who are depressed (or have symptoms of depression) may have difficulty doing their job effectively; they may experience stressors such as problems with their coworkers and supervisors, job insecurity, or financial worries. In such cases, the depressive symptoms may *cause* the stressful life events. Alternatively, some people, by virtue of their temperament, may seek out situations or experiences that are stressful; for example, some soldiers volunteer to go to the front line (Foley, Neale, & Kendler, 1996; Lyons et al., 1993). The point is that the relationship between stressful life events and depression may not be as straightforward as it might seem.

In a longitudinal study examining the relationship between stressful life events and depression among teenagers, researchers found that participants who had three or more stressful life events in the previous year were more likely to

Bonnie Kamin/Photo Edit

Researchers are trying to interpret the correlation between stressful life events and depression. Although stressful events may lead to depression, the symptoms of depression—such as a lack of energy, social isolation, and reduced productivity at work—can create stressful events. For instance, a man who is self-employed may be unable to maintain his usual level of work, so his income drops and financial worries increase.

develop depression than were those with fewer than three such events (Lewinsohn et al., 1999). Another study that examined the relationship between different types of stressful life events and subsequent depression among teenagers found that the recent breakup of a love relationship was the life event most closely associated with a first episode of depression (Monroe et al., 1999).

Several theories have been offered to explain how stressful life events can trigger depression in vulnerable people. Some researchers propose that such events can lead an individual to focus on discrepancies between the “real” and “ideal” selves; for example, the person’s “ideal” self of being lovable or worthwhile may be challenged when a love relationship ends (Pyszczynski & Greenberg, 1987). Focusing on this kind of discrepancy can also happen after an injury or illness challenges the invulnerability of the “ideal” self. A person then tries to resolve the discrepancy between the “real” and “ideal” selves (perhaps by changing his or her concept of ideal self to one that isn’t so lovable). When attempts to resolve the discrepancy are unsuccessful, a person may continue to focus on the discrepancy and become depressed. Later, we will discuss how the “stress” and “diathesis” parts of the stress-diathesis model relate to each other, and how they trigger a cascade of neurological events associated with depression.

Social Exclusion

Feeling the chronic sting of social exclusion—being pushed toward the margins of society—is also associated with depression. For instance, those who are the targets of prejudice, such as homosexuals who experience community alienation or violence (Mills et al., 2004), and those from lower socioeconomic groups (Field, Hernandez-Reif, & Diego, 2006; Henderson et al., 2005; Inaba et al., 2005), including the elderly (Hybels et al., 2006; Sachs-Ericsson, Plant, & Blazer, 2005), are more likely than others to become depressed.

Some studies find that Latinos and African Americans experience more depression than other ethnic groups in the United States; a closer look at the data, however, suggests that socioeconomic status, rather than ethnic or racial background, is the variable associated with depression (Bromberger et al., 2004; Gilmer et al., 2005). (Note that these individuals can be members of more than one group simultaneously.) People who become disabled in adulthood, through stroke or head trauma, are also more likely than others to become depressed (McDermott et al., 2005).

Social Interactions

To a certain extent, emotions can be contagious: People can develop depression, sadness, anxiety, or anger by spending time with someone who is already in such a state (Coyne, 1976; Hsee et al., 1990; Joiner, 1994; Segrin & Dillard, 1992; Sullins, 1991). For instance, one study found that roommates developed symptoms of depression after 3 weeks of living with someone who was depressed (Joiner, 1994).

Another factor associated with depression is the way some people typically interact in their personal relationships (Ainsworth et al., 1978; Bowlby, 1973, 1979). Patterns of *attachment* have been identified; such patterns begin in infancy and are partly based on the consistency and quality of the caregiver’s interactions with the child. When infants are distressed, they tend to display one of the following three patterns that typically endure through adulthood:

1. *Secure attachment*, or seeking out and using a caregiver for comfort and support. (Adults with this style generally display a positive relationship style.)
2. *Avoidant attachment*, or actively avoiding the caregiver. (Adults with this style are emotionally distant from others.)

David Young-Wolff/Photo Edit

The quality of the bond between elderly partners can buffer against the negative effects of stressful life events (Kraaij & Garnefski, 2002).

3. *Anxious-ambivalent attachment*, or alternating between seeking support from the caregiver and withdrawing, often displaying anger. (Adults with this style chronically worry about their relationships.)

Adults who are characterized by the two insecure forms of attachment are more vulnerable to depression: Those with anxious-ambivalent attachment are the most likely to experience episodes of depression, followed by those with avoidant attachment. Adults with secure attachment are least likely to do so (Bifulco et al., 2002; Cooper, Shaver, & Collins, 1998; Fonagy et al., 1996).

Culture

A person's culture and context can influence how the person experiences and expresses depressive symptoms (Lam, Marra, & Salzinger, 2005). For instance, in Asian or Latin cultures, people with depression may not mention mood, but talk about "nerves" or describe headaches. Similarly, depressed people in Zimbabwe tend to complain about fatigue and headaches (Patel et al., 2001). In contrast, some depressed people from Middle Eastern cultures may describe problems with their heart, and depressed Native Americans of the Hopi people may report feeling heart-broken (American Psychiatric Association, 2000).

The influence of culture doesn't end with the way symptoms are described. Each culture—and subculture—also leads its members to take particular symptoms more or less seriously. For instance, in cultures that have strong prohibitions against suicide, having suicidal thoughts is a key symptom; in cultures that emphasize being productive at work, having difficulty functioning well at work is considered to be a key symptom (Young, 2001).

A particular culture can also be influenced by another culture and change accordingly. Consider that depressed people in China have typically reported mostly physical symptoms of depression, but these reports are changing as China becomes increasingly exposed to Western views of depression (Parker, Gladstone, & Chee, 2001).

Gender Difference

In North America, women are about twice as likely as men to be diagnosed with depression (American Psychiatric Association, 2000; Marcus et al., 2005), and studies in Europe find a similar gender difference (Angst et al., 2002; Dalgard et al., 2006). Research results indicate that the gender difference arises at puberty and continues into adulthood (Alloy & Abramson, 2007; Jose & Brown, 2008).

What might cause the gender difference? One explanation focuses on a ruminative response to stress: women are more likely than men to mull over a stressful situation, whereas men more often respond by distracting themselves and taking action (Nolen-Hoeksema, 1987; Nolen-Hoeksema & Morrow, 1993; Vajk et al., 1997). A ruminative pattern can be unlearned: College students who learned to use distraction more and rumination less improved their depressed mood (Nolen-Hoeksema & Morrow, 1993).

Another explanation for the gender difference in rates of depression is that girls' socialization into female roles can lead them to experience more body dissatisfaction, which in turn can make them more vulnerable to automatic negative thoughts that lead to depression (Cyranowski et al., 2000; Nolen-Hoeksema & Girgus, 1994). Another consideration is that women may be more likely than men to *report* symptoms of depression, although not necessarily to *experience* more of these symptoms (Sigmon et al., 2005). Such a bias in reporting symptoms isn't limited to self-reports: Family members are more likely to report female relatives as seeming depressed, even when the females themselves did not report feeling depressed (Brommelhoff et al., 2004).

David Young-Wolff/Photo Edit

Culture influences which symptoms of depression people experience, express, and worry about most.

Note also that biological differences—such as specific female hormonal changes involved in puberty—may contribute to this gender difference (Halbreich & Kahn, 2001; Steiner, Dunn, & Born, 2003). A role for this biological factor is consistent with the finding that, before puberty, boys and girls have similar rates of depression (Cohen et al., 1993). Additional evidence that hormones influence depression is the fact that women and men have similar rates of the disorder after women have reached menopause (and hence their levels of female hormone are greatly reduced; Hyde, Mezulis, & Abramson, 2008).

The different explanations for the gender difference are not mutually exclusive, and these factors may interact with one another (Hyde, Mezulis, & Abramson, 2008). For instance, girls who enter puberty early are more likely to become depressed (Kaltiala-Heino, Kosunen, & Rimpela, 2003), perhaps in part because their early physical development makes them more likely to be noticed and teased about their changing bodies, which in turn can lead to dissatisfaction with and rumination about their bodies. Let's examine more broadly how feedback loops contribute to depression.

FEEDBACK LOOPS IN ACTION: Depressive Disorders

How do neurological, psychological, and social factors interact through feedback loops to produce depression? As we noted earlier in the section on genetics, some people are more vulnerable to stress. For these people, the HPA axis is highly responsive to stress (and often the stress is related to social factors). For example, abuse or neglect at an early age, with accompanying frequent or chronic increase in the activity of the HPA axis, can lead cortisol-releasing cells to overrespond to any stressor—even mild ones (Nemeroff, 1998). In fact, college students with a history of MDD reported feeling more tension and responded less well after a stressful cognitive task (one that, unknown to these participants, was impossible to solve) than college students with no history of MDD (Ilgen & Hutchison, 2005). These results support the notion that stressors affect people vulnerable to MDD differently than they affect those without such a vulnerability (Hasler et al., 2004).

A cognitive factor that makes a person vulnerable to depression, such as a negative attributional style, a ruminative coping style, or dysfunctional thoughts (all psychological factors), can amplify the negative effects of a stressor. In fact, such cognitive factors can lead people to be hypervigilant for stressors or to interpret neutral events as stressors, which in turn activates the HPA axis. This neurological response then can lead such individuals to interact differently with others (social factor)—making less eye contact, being less responsive, and becoming more withdrawn.

Researchers have identified other ways that neurological, psychological, and social factors create feedback loops in depression. According to James Coyne's interactional theory of depression (Coyne, 1976; Coyne & Downey, 1991; Joiner, Coyne, & Blalock, 1999), someone who is neurologically vulnerable to depression (perhaps because of genes or neurotransmitter abnormalities) may, through verbal and nonverbal behaviors (psychological factor), alienate people who would otherwise be supportive (social factor; Nolan & Mineka, 1997). Such behaviors could arise from negative

attributions and views about self and the environment (psychological factors), which in turn could arise from group interactions (social factors), such as being teased or ridiculed, or modeling the behavior of someone else. When someone who is depressed expresses consistently negative attitudes, exhibits a pattern of ignoring or failing to benefit from the help of others, or seems to become too

Image Source/Jupiterimages

Girls are typically encouraged to cope with stressors by ruminating. In contrast, boys are typically encouraged to use activity and distraction. This gender difference may contribute to the higher rate of depression among women than among men (Nolen-Hoeksema, 1987, 2001).

dependent on others, other people may eventually criticize and even reject the person, which could have the effect of confirming the person's negative view of self and his or her prospects for the future. Consider that researchers have found that depressed undergraduates are more likely than nondepressed undergraduates to solicit negative information from happy people; such a tendency can lead happier people to reject the depressed questioner, confirming negative beliefs about himself or herself (Wenzlaff & Beevers, 1998).

In short, people's psychological characteristics affect how they interpret events and how they behave, which in turn influences how they are treated in social interactions, which then influences their beliefs about themselves and others (Casbon et al., 2005). And all of this is modulated by whether or not the person is neurologically vulnerable to depression. Figure 6.2 illustrates the feedback loops.

Treating Depressive Disorders

As discussed in Chapter 4, different treatments target different factors. However, successful treatment of any one factor will affect the others. For example, improving disrupted brain functioning will alter a person's thoughts, mood, and behavior, and interactions with others.

Targeting Neurological Factors

In treating depressive disorders, clinicians rely on two major types of treatment that directly target neurological factors: medication and brain stimulation.

Medication

Several types of medications are commonly prescribed for depression; it can take weeks for one of these medications to bring about any change in depressed mood. Antidepressant medications include the following:

- **Selective serotonin reuptake inhibitors (SSRIs)**, such as *fluoxetine* (Prozac), *paroxetine* (Paxil), and *sertraline* (Zoloft). SSRIs slow the reuptake of serotonin from synapses. Because these antidepressants affect only certain receptors, they have fewer side effects than other types, which can make people less likely to stop taking them (Anderson, 2000; Beasley et al., 2000). However, SSRIs are the only type of antidepressant to have the side effect of decreased sexual interest, which can lead some patients to stop taking them (Brambilla et al., 2005; Gregorian et al., 2002). Many patients also find that the same dose of an SSRI brings less benefit over time (Arana & Rosenbaum, 2000)—an effect nicknamed *Prozac poop-out*. SSRIs are also used to treat anxiety disorders, (discussed in Chapter 7), as well as other disorders.
- **Tricyclic antidepressants (TCAs)**, such as *amitriptyline* (Elavil). TCAs are so named because their molecular structure contains three (*tri-*) rings of atoms; they have been used since the 1950s to treat depression and, until SSRIs became available, were the type of medication most commonly used for this purpose. TCAs are generally as effective as Prozac for depression (Agency for Health Care Policy and Research, 1999). The side effects of TCAs differ from those of SSRIs: The most common side effects include low blood pressure, blurred vision, dry mouth, and constipation, but diminished libido (sex drive) is not a significant side effect (Arana & Rosenbaum, 2000).
- **Monoamine oxidase inhibitors (MAOIs)**, such as *phenelzine* (Nardil). Some neurotransmitters, such as serotonin, dopamine, and norepinephrine, are classified as *monoamines*; monoamine oxidase is a naturally produced enzyme that breaks down monoamines in the synapse. MAOIs inhibit this chemical breakdown, so the net effect is to increase the amount of neurotransmitter in the synapse. MAOIs are more effective for treating atypical depression (Cipriani et al., 2007; Prien & Kocsis, 1995) than typical depression. These medications can be dangerous when patients

Selective serotonin reuptake inhibitors (SSRIs)

Medications that slow the reuptake of serotonin from the synapse.

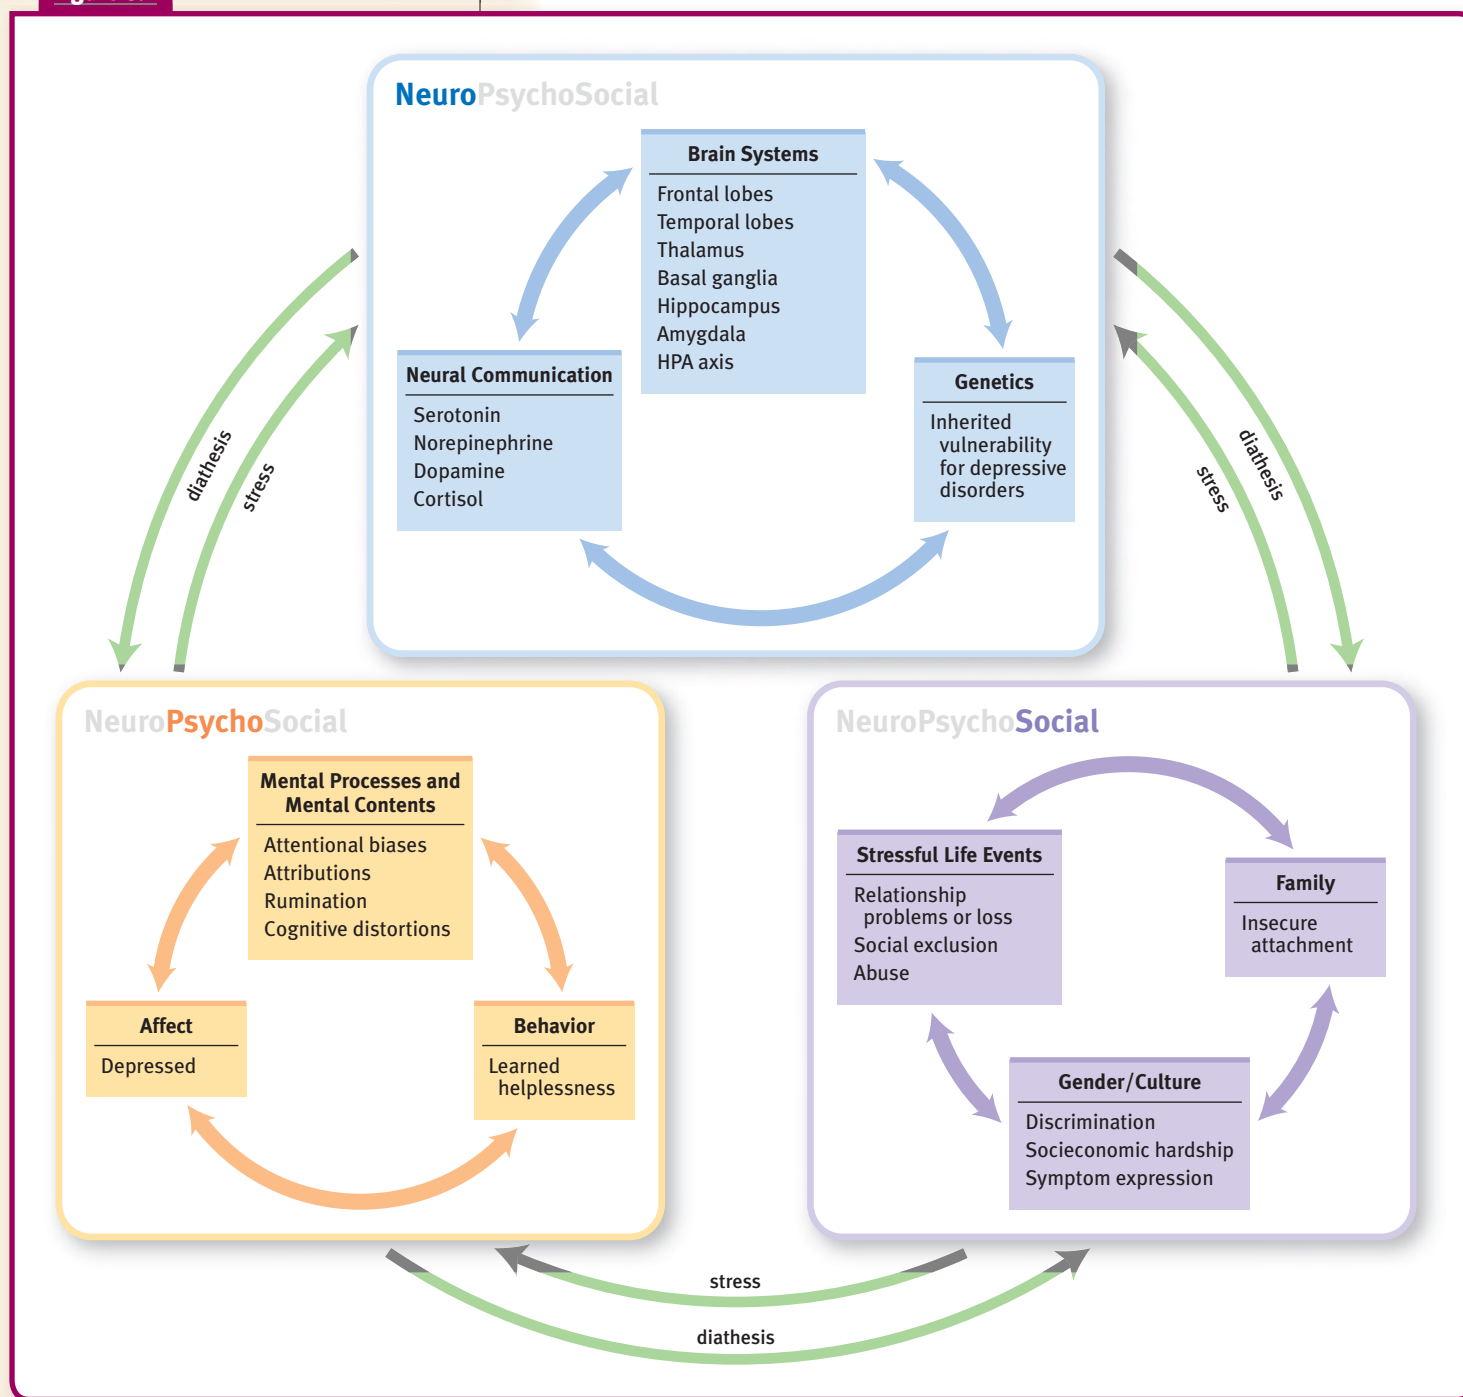

Tricyclic antidepressants (TCAs)

Older antidepressants named after the three rings of atoms in their molecular structure.

Monoamine oxidase inhibitors (MAOIs)

Antidepressant medications that increase the amount of monoamine neurotransmitter in the synapse.

6.2 ► Feedback Loops in Action: Depressive Disorders

eat foods (such as wine and cheese) containing a substance called tyramine, which can cause fatal blood pressure changes. An MAOI is now available as a skin patch; the skin patch method of administering the medication avoids absorption via the gastrointestinal tract and thus reduces the risk associated with eating tyramine-rich foods (Patkar, Pae, & Masand, 2006).

Among the antidepressants, SSRIs have been the most popular, in part because they have the fewest side effects. By 2004, however, mental health professionals and

laypeople raised concerns about whether SSRI use was associated with increased suicide rates. Studies comparing SSRIs to other antidepressants did, in fact, find a greater risk for suicidal thoughts and suicide attempts in children and adolescents taking such medications (Martinez et al., 2005); these findings led to a “black box” warning label, indicating that the medications may increase the risk of suicide in children who take them and that the children should be closely monitored for suicidal thoughts or behavior or for an increase in depressive symptoms. Since the warning label was mandated, additional research suggests that the benefits of SSRI antidepressants for youngsters outweigh any risk of suicide, although people taking them should continue to be carefully monitored (Bridge et al., 2007). Although studies of adults did not find an increased suicide risk with SSRIs generally (Fergusson et al., 2005; Gunnell, Saperia, & Ashby, 2005), they did find an increased suicide risk with the SSRI *paroxetine* (Paxil) (Aursnes et al., 2005). Moreover, studies of SSRI use by adults revealed an increased risk of nonlethal self-harming behavior (Martinez et al., 2005; Tihonen et al., 2006).

Medications for depression are continually being developed. Researchers seek to minimize the side effects of existing medications and to create new drugs for people who do not get sufficient relief from existing ones. For instance, some newer antidepressants, such as *venlafaxine* (Effexor) and *duloxetine* (Cymbalta), affect neurons that respond both to serotonin and norepinephrine; such medications are sometimes referred to as *serotonin/norepinephrine reuptake inhibitors* (SNRIs). Some other new antidepressants that affect noradrenaline (the alternative term for norepinephrine) and serotonin are referred to as *noradrenergic and specific serotonergic antidepressants* (NaSSAs, where Na stands for “noradrenergic”). The antidepressant *mirtazapine* (Remeron) is a NaSSA.

Clinicians may also prescribe any of the antidepressants discussed above for dysthymia. The decision regarding which antidepressant to prescribe for any depressive disorder is not yet based entirely on science—it is not presently possible to predict which antidepressant will be the most effective with the least side effects for a given individual (assuming that medication is the preferred treatment). Being able to predict side effects is important because they often lead patients to stop the medication. In fact, a majority of patients who receive medication for depression stop taking the medication before it has had a chance to be maximally effective either within the first few weeks, before it can take full effect, or during an extended period of better mood (Aikens, Nease, & Klinkman, 2008; National Committee for Quality Assurance, 2007).

Some people with depression who do not want to take prescription medication have successfully used an extract from a flowering plant called St. John's wort (*Hypericum perforatum*). Results of meta-analytic studies comparing St. John's wort to prescription antidepressants and placebos indicate that the herbal medication can help those with mild to moderate depression, and sometimes—but less commonly—even those with severe depression (Linde, Berner, & Krison, 2008; Linde et al., 2005). Patients taking St. John's wort report fewer side effects than do patients taking prescription medications (Linde, Berner, & Krison, 2008); the most common side effect is dry mouth or dizziness.

Another medication for which a prescription is not necessary is *ademetionine*, or *S-adenosyl-L-methionine* (SAME), which was found to be as effective as the TCA imipramine and superior to a placebo (Agency for Health Care Policy and Research, 2002; Pancheri, Scapicchio, & Dell Chiaie, 2002). SAME has been reported to reduce depression more quickly than other antidepressants—in about a week.

Valerie Giles/Photo Researchers

Don Farrall/Getty Images

St. John's wort, shown here as the plant and in capsule form, may lessen mild to moderate depression but may not be as effective as antidepressant medication for those with severe MDD (Linde et al., 2005).

Eighty percent of all ECT treatment is given for depression (Sackheim et al., 1995).

Brain Stimulation

Not all patients with depression are helped by medication or by other commonly employed treatments, such as cognitive-behavior therapy (CBT). Electroconvulsive therapy (ECT; see Chapter 4) may be used when a patient's symptoms are severe and he or she (1) cannot take medication because of side effects or other medical reasons, (2) has a psychotic depression (depression with psychotic features) that does not respond to medication (Fink, 2001), or (3) has severe depression that has not improved significantly with either medication or psychotherapy (Lam et al., 1999). Unfortunately, some people receiving ECT suffer memory loss for events that occurred during a brief period of time before the procedure (Kho, VanVreeswijk, & Murre, 2006).

ECT for depression is usually administered 2 to 3 times a week over several weeks, for a total of 6 to 12 sessions (Shapira et al., 1998; Vieweg & Shawcross, 1998). Depressive symptoms lessen a few weeks after the treatment begins, although scientists don't yet understand exactly how ECT provides relief (Pagnin et al., 2004).

Unfortunately, depressed patients who hadn't responded to antidepressants commonly relapse after receiving ECT: At least half of these patients experience another episode of depression over the following 2 years (Gagne et al., 2000; Sackheim et al., 2001). To minimize the risk of a relapse, patients usually begin taking antidepressant medication after ECT ends. Some research suggests that relapse may be best prevented by beginning antidepressant medication *during* the course of ECT—rather than afterward—and by continuing ECT at a maintenance level (weekly sessions tapering to monthly sessions) for several months after the standard course of treatment is completed (Gagne et al., 2000).

Some patients with depression might benefit from transcranial magnetic stimulation (TMS; see Chapter 4), which involves sending high-intensity magnetic pulses through the brain. In some encouraging studies, about half of the depressed patients who did not improve with medication were treated successfully enough with TMS that they did not have to receive ECT (Epstein et al., 1998; Figiel et al., 1998; Klein et al., 1999). TMS is easier to administer and causes fewer side effects than ECT. However, unlike ECT, researchers have yet to establish definitive guidelines for TMS that govern critical features of the treatment, such as the positioning of the coils that deliver magnetic pulses and how often the treatment should be administered (Holtzheimer & Avery, 2005). In 2008, the Federal Drug Administration approved TMS as a treatment for depression to be used after medication treatments have failed.

Targeting Psychological Factors

Biomedical treatments are not the only ones available for depression. A variety of treatments are designed to alter psychological factors—changing the patient's behaviors, thoughts, and feelings.

Behavioral Methods

Behavioral methods focus on identifying depressive behaviors and then changing them. For instance, being socially isolated and avoiding daily activities can lead to depressive thoughts and feelings or can help maintain them (Emmelkamp, 1994). Changing these depressive behaviors can, in turn, increase the opportunities to receive positive reinforcement (Lewinsohn, 1974). Specific techniques to change depressive behaviors, collectively referred to as *behavioral activation* (Gortner et al., 1998), include self-monitoring, scheduling daily activities that lead to pleasure or a sense of mastery, and identifying and decreasing avoidant behaviors. Behavioral activation may also include problem solving—identifying obstacles that interfere with achieving a goal and then developing solutions to

circumvent or eliminate those obstacles. For instance, a depressed college student may feel overwhelmed at the thought of asking for an extension for an already overdue paper. The student and therapist work together to solve the problem of how to go about asking for the extension—they come up with a realistic timetable to complete the paper and discuss how to talk with the professor. Behavioral activation techniques may initially feel aversive to a person with depression because they require more energy than he or she feels able to summon; however, mood improves in the long term. In fact, behavioral activation is superior to cognitive techniques in treating both moderate and severe depression (Dimidjian et al., 2006).

Cognitive Methods

Based on the premise that depressing thoughts lead to similar feelings and behaviors, cognitive methods aim to diminish or change such thoughts, which are often distortions of reality (see Chapter 4). Patients are encouraged to conduct their own experiments by collecting data to assess the accuracy of their beliefs, which are often irrational and untrue (Hollon & Beck, 1994). This process can relieve some patients' depression, and can prevent or minimize further episodes of depression (Teasdale & Barnard, 1993; Teasdale et al., 2002).

Consider Kay Jamison: She felt that she was a burden to her friends and family, and that they would all be better off if she were dead. Cognitive therapy would explore the accuracy of these beliefs: Why did she think she was a burden? What evidence did she have to support this conclusion? How might friends or family react if she told them that they'd be better off if she were dead? A cognitive therapist might even suggest that she talk to them about her beliefs and listen to their responses—was she accurate in her beliefs? Most likely, her friends and family would *not* agree that they'd be better off if she were dead.

However, successful short-term cognitive therapy is not necessarily a permanent cure. A meta-analysis of studies of manual-based, short-term therapy (usually 12–20 sessions) found that although CBT decreased symptoms, many patients still had significant symptoms at the conclusion of the treatment and were at risk for relapse. Of the patients who had improved, only about 35% retained that degree of improvement 18 months later; the others had at least some relapse of their depressive symptoms (Westen & Morrison, 2001).

Cognitive-Behavior Therapy Compared to Medication

CBT, particularly when it includes behavioral activation, is often about as successful as medication (Dimidjian et al., 2006; DeRubeis et al., 2005; Sava et al., 2009; TADS Team, 2007). In some ways CBT may be better than medication: The side effects of medication may lead patients to stop taking it; various studies have found that about 75% of patients either stop taking their antidepressant medication within the first 3 months, or they take less than an optimal dose (Mitchell, 2007). And when patients stop taking medication, a high proportion of them relapse. Furthermore, even when medication is successful, some research suggests that people at risk for further episodes should continue to take the medication for the rest of their lives to prevent relapses (Hirschfield et al., 1997).

In contrast, the beneficial effects of CBT can persist after treatment ends (Hollon et al., 2005); CBT is an alternative that need not be administered for life. Moreover, medication and CBT can be used together. In fact, studies have shown that a combination of medication and CBT is more effective than medication alone—even for severely depressed adolescents and adults (Macaskill & Macaskill, 1996; TADS Team, 2007; Thase et al., 1997). In addition, after treatment with antidepressants has ended, a patient's residual symptoms of depression can be reduced through CBT; this supplemental CBT can reduce the relapse rate (Fava et al., 1998a, 1998b).

Targeting Social Factors

Treatment for depression can also directly target a social factor—personal relationships. Such treatment is designed to increase the patient’s positive interactions with others and minimize the negative interactions.

Spencer Grant/Photo Edit

Interpersonal therapy seeks to improve patients’ relationships, and thereby alleviate depression.

Interpersonal Therapy

Interpersonal therapy for depression (IPT, explained in Chapter 4) emphasizes the links between mood and events in a patient’s recent and current relationships (Klerman et al., 1984). Relationships that function poorly can contribute to poor mood and depression, and improved relationships can reduce depression. IPT addresses four general aspects of relationships, generally in about 16 sessions:

- a deficiency in social skills or communication skills, which results in unsatisfying social relationships;
- persistent, significant conflicts in a relationship;
- grief about a loss; and
- changes in interpersonal roles (for example, a partner with a new job may have become less emotionally available).

IPT is effective in a wide range of circumstances and settings. For example, in an innovative study of depressed people in 30 Ugandan rural villages, researchers randomly assigned depressed residents from 15 villages to group IPT, consisting of 16 weeks of 90-minute sessions. The depressed residents from the other 15 villages received no treatment (the control group). Those who received group IPT had a significant decrease in their depressive symptoms (and were better able to provide for their families and participate in community activities) than those in the control group (Bolton et al., 2003). IPT has also successfully reduced the occurrence of postpartum depression in pregnant women at high risk for the disorder (Zlotnick et al., 2006). In addition to alleviating depressive symptoms, maintenance IPT—either alone or in combination with CBT—may also prevent relapse (Frank et al., 2007; Klein et al., 2004).

Family Systems Therapy

A family’s functioning may be a target of treatment; this usually occurs when a family member’s depression is related to either a maladaptive pattern of interaction within the family or a conflict that arose within the family. Conflicts—particularly over values—may arise within families that have immigrated to the United States; immigrant parents and their children who grow up in the United States may experience tension because what the parents want for their children conflicts with what the children (as they become adults) want for themselves. Immigrant parents from Mexico, for instance, may want to be very involved in their children’s lives, just as they would be in their native hometown. But their children, growing up in the United States, may come to resent what the children perceive of as their parents’ intrusive and controlling behavior (compared to the parents of their peers; Santisteban et al., 2002). The parents, in turn, may think that their children are rejecting both their Mexican heritage and the parents themselves. Caught between two cultures—the old and the new—and wanting to maintain aspects of their heritage but also feel “American,” the resulting conflict can contribute to depression (Hovey, 1998, 2000; Hovey & King, 1996). Family systems therapy might help family members to talk about and understand the cultural and personal meaning of each others’ behavior.

A similar cultural conflict can develop when members of a couple bump up against each other’s different backgrounds (Baltas & Steptoe, 2000). As Ruben and Angie in Case 4.2 discovered, systems therapy can help clarify such a conflict and find adaptive ways to resolve it.

FEEDBACK LOOPS IN TREATMENT: **Depressive Disorders**

The goals of any treatment for depressive disorders are ultimately the same:

- to reduce symptoms of distress and depressed mood and negative or unrealistic thoughts about the self (psychological factors),
- to reduce problems related to social interactions—such as social withdrawal—and to make social interactions more satisfying and less stressful (social factors), and
- to correct imbalances in the brain associated with some of the symptoms, such as by normalizing neurotransmitter functioning or hormone levels (neurological factors).

Treatments that target one type of factor also affect other factors. CBT, for instance, not only can lessen psychological symptoms, but can also change brain activity (Goldapple et al., 2004), improve physical symptoms (including disrupted sleep, appetite, and psychomotor symptoms), and improve social relations. Moreover, as we saw in Chapter 5, medication for depression works not just through its effects on neurological functioning, but also through the placebo effect. Thus, a depressed patient's beliefs (psychological factor) can account for much of the effect of antidepressant medication. Figure 6.3 illustrates the various treatments discussed; the targets of treatments for depressive disorders, and the feedback loops that arise with successful treatment.

Note that Figure 6.3 lists the various types of treatment for depressive disorders, sorted into the three types of factors; in two cases—medication and CBT—we go one step further and list specific types of drugs and specific CBT methods. Why are we

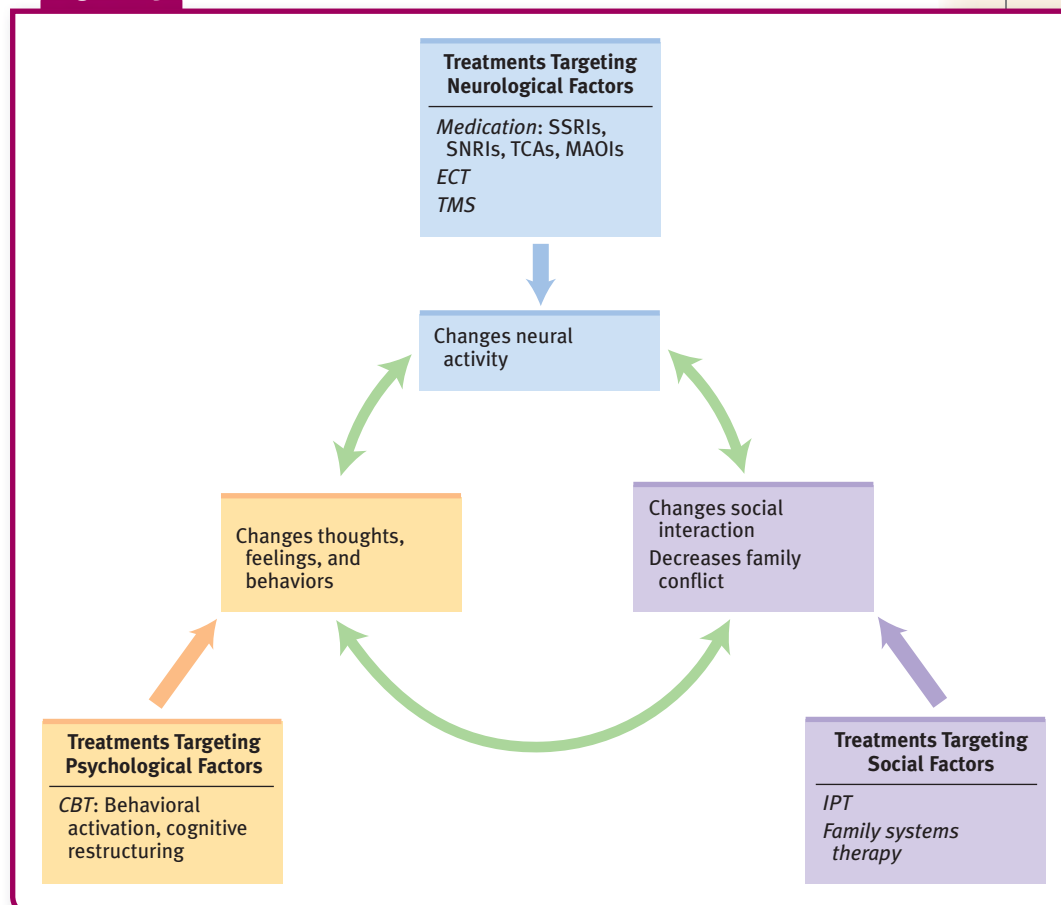

Figure 6.3

specific with only these two forms of treatment? Because the forms of treatment have been studied the most extensively, and hence more is known about which specific medications and CBT methods are most likely to reduce symptoms and improve quality of life. Rigorous studies of other types of treatments are less common, and hence less is known about the specific methods that are most likely to be effective. You will find this same disparity in knowledge reflected in subsequent figures that illustrate feedback loops of treatments for other disorders.

Now that we've discussed depressive disorders, let's look back at what we know about Kay Jamison thus far, and see whether MDD is the diagnosis that best fits her symptoms: She experienced depressed moods, anhedonia, fatigue, and feelings of worthlessness. She also had recurrent thoughts of death, as well as difficulty concentrating. Taken together, these symptoms seem to meet the criteria for MDD. However, she also has symptoms that may be building blocks for the diagnosis of another mood disorder. If her symptoms meet the criteria for any of those building blocks, her diagnosis would change. We examine those building blocks in the next section.

Key Concepts and Facts About Depressive Disorders

- A major depressive episode (MDE) is the building block for a diagnosis of major depressive disorder (MDD): When a person has an MDE, he or she is diagnosed with MDD. Symptoms of an MDE can arise in three areas: affect (anhedonia, weepiness, and decreased sexual interest), behavior (vegetative signs), and cognition (sense of worthlessness or guilt, difficulty concentrating, and recurrent thoughts of death or suicide). Most people who have an MDE return to their premorbid level of functioning after the episode, but some people will have symptoms that do not completely resolve even after several years.
- Depression is becoming increasingly prevalent in younger cohorts. Depression and anxiety disorders have a high comorbidity—around 50%.
- MDD may arise with melancholic features, catatonic features, or psychotic features. Symptoms may also fall into less common patterns, as in atypical depression and chronic depression. In some cases, depression is related to pregnancy and giving birth (postpartum onset) or to seasonal changes in light (seasonal affective disorder).
- A diagnosis of dysthymic disorder requires fewer symptoms than does a diagnosis of MDD; however, the symptoms of dysthymic disorder must persist for a longer time than do symptoms of MDD. People with both dysthymic disorder and MDD are said to have double depression.
- Neurological factors related to depression include low activity in the frontal lobes, and implicate abnormal functioning of various neurotransmitters (dopamine, serotonin, and norepinephrine). The stress–diathesis model of depression highlights the role of increased activity of the HPA axis and of excess cortisol in the blood; an overreactive HPA axis is thought to affect serotonin activity and impair the functioning of the hippocampus. People with atypical depression have the opposite pattern—decreased activity of the HPA axis. Genes can play a role in depression, perhaps by causing a person to have disrupted sleep patterns or by influencing how an individual responds to stressful events, which in turn affects activity of the HPA axis.
- Psychological factors that are associated with depression include a bias toward paying attention to negative stimuli, dysfunctional thoughts (including cognitive distortions related to the negative triad of depression), rumination, a negative attributional style (particularly attributing negative events to internal, global, and stable factors), and learned helplessness.
- Social factors that are associated with depression include stressful life events, social exclusion, and problems with social interactions or relationships (particularly for people who have an insecure attachment). Culture and gender can influence the specific ways that symptoms of depression are expressed.
- Neurological, psychological, and social factors can affect each other through feedback loops, as outlined by the stress–diathesis model and Coyne's interactional theory of depression. According to the stress–diathesis model, abuse or neglect during childhood (a stressor) and increased activity in the HPA axis can lead to overreactive cortisol-releasing cells (a diathesis), which respond strongly to even mild stressors. Psychological factors can create a cognitive vulnerability to depression, which in turn can amplify the negative effects of a stressor and change social interactions. Coyne's theory proposes that among neurologically vulnerable people, their depression-related behaviors may alienate other people, producing social stressors.
- Biomedical treatments that target neurological factors for depressive disorders are medications (SSRIs, TCAs, MAOIs, SNRIs, St. John's wort, and SAMe) and brain stimulation (ECT or TMS).
- Treatments for depression that target psychological factors include CBT (particularly with behavioral activation).
- Treatments that target social factors include IPT and family systems therapy.

Making a Diagnosis

- Reread Case 6.1 about William Styron, and determine whether or not his symptoms meet the criteria for an MDE. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 6.2 about Marie Osmond, and determine whether or not her symptoms meet the criteria for MDD, postpartum onset. Specifically, list which criteria apply and which

do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

- Reread Case 6.3 about Mr. A, and determine whether or not his symptoms meet the criteria for dysthymic disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Bipolar Disorders

After receiving her Ph.D. in psychology and joining the faculty of the Department of Psychiatry at UCLA, Kay Jamison went to a garden party for faculty. The man who would later become her psychiatrist was there, and years later they discussed the party:

My memories of the garden party were that I had a fabulous, bubbly, seductive, assured time. My psychiatrist, however, in talking with me about it much later, recollected it very differently. I was, he said, dressed in a remarkably provocative way, totally unlike the conservative manner in which he had seen me dressed over the preceding year. I had on much more makeup than usual and seemed, to him, to be frenetic and far too talkative. He says he remembers having thought to himself, Kay looks manic. I, on the other hand, had thought I was splendid.

(Jamison, 1995, p. 71)

The other set of mood disorders is **bipolar disorders**—in which a person's mood is often persistently and abnormally upbeat or shifts inappropriately from upbeat to markedly down. (Bipolar disorders were previously referred to as *manic-depressive illness* or simply *manic-depression*.) Jamison's behavior at the garden party indicates the opposite of depression—mania.

Building Blocks for Bipolar Disorders

Diagnoses of bipolar disorders are based on four building blocks, which are types of mood episodes. These four building blocks are major depressive episode (the building block of MDD), *manic episode*, *mixed episode*, and *hypomanic episode*. The configuration of an individual's particular mood episodes determines not only the diagnosis, but also the treatment and prognosis.

Manic Episode

The hallmark of a **manic episode**, such as the one Jamison apparently had when at the garden party, is a discrete period of at least 1 week of abnormally euphoric feelings, intense irritability, or an *expansive mood*. During an **expansive mood**, the person exhibits unceasing, indiscriminate enthusiasm for interpersonal or sexual interactions or for projects. The expansive mood and related behaviors contrast with the individual's usual state. For instance, a normally shy individual may, during a manic episode, have extensive, intimate conversations with strangers in public places. For some, though, the predominant mood during a manic episode may be irritability. Alternatively, during a manic episode, a person's mood can shift between abnormal and persistent euphoria and irritability, as it did for Jamison:

There is a particular kind of pain, elation, loneliness, and terror involved in this kind of madness. When you're high, it's tremendous. The ideas and feelings are fast and frequent like shooting stars, and you follow them until you find better and brighter ones. Shyness goes, the right words and gestures are suddenly there, the power to

Bipolar disorders

Mood disorders in which a person's mood is often persistently and abnormally upbeat or shifts inappropriately from upbeat to markedly down.

Manic episode

A period of at least 1 week characterized by abnormal and persistent euphoria or expansive mood or irritability.

Expansive mood

A mood that involves unceasing, indiscriminate enthusiasm for interpersonal or sexual interactions or for projects.

captivate others a felt certainty. There are interests found in uninteresting people. Sensuality is pervasive and the desire to seduce and be seduced irresistible. Feelings of ease, intensity, power, well-being, financial omnipotence, and euphoria pervade one's marrow. But, somewhere, this changes. The fast ideas are far too fast, and there are far too many; overwhelming confusion replaces clarity. Memory goes. Humor and absorption on friends' faces are replaced by fear and concerns. Everything previously moving with the grain is now against—you are irritable, angry, frightened, uncontrollable, and enmeshed totally in the blackest caves of the mind. You never knew those caves were there. It will never end, for madness carves its own reality.

(1995, p. 67)

Table 6.7 lists the criteria for a manic episode.

Table 6.7 ▶ DSM-IV-TR Diagnostic Criteria for a Manic Episode

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 1 week (or any duration if hospitalization is necessary).

B. During the period of mood disturbance, three (or more) of the following symptoms have persisted (four if the mood is only irritable) and have been present to a significant degree:

- (1) inflated self-esteem or grandiosity
- (2) decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
- (3) more talkative than usual or pressure to keep talking
- (4) flight of ideas or subjective experience that thoughts are racing
- (5) distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
- (6) increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
- (7) excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)

C. The symptoms do not meet criteria for a mixed episode [discussed later in the chapter].

D. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.

E. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).

Note: Manic-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of bipolar I disorder [discussed later in the chapter].

Source: Reprinted with permission from the DSM-IV-TR Casebook: A Learning Companion to the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision, (Copyright 2002) American Psychiatric Association.

As noted in Table 6.7, in a manic episode, a person may begin projects (one type of goal-directed activity, see criterion B6 in Table 6.7), even though he or she doesn't possess the special knowledge or training required to complete the project; for instance, the person might try to install a dishwasher, despite knowing nothing about plumbing. Moreover, when manic, some people are uncritically grandiose—often believing themselves to have superior abilities or a special relationship to political or entertainment figures; these beliefs may reach delusional proportions, to the point where an individual may stalk a celebrity, believing that he or she is destined to marry that famous person.

During a manic episode, a person needs much less sleep—so much less that he or she may be able to go for days without it, yet not feel tired. Similarly, when manic, the affected person may speak rapidly or loudly and may be difficult to interrupt; he or she may talk nonstop for hours on end, not letting anyone else get a word in edgewise. Moreover, when manic, the individual rarely sits still (Cassano

et al., 2009). Another symptom of mania is a **flight of ideas**, thoughts that race faster than they can be said. When speaking while in this state of mind, the person may flit from topic to topic, as illustrated in Case 6.4; flight of ideas has commonly been described as something like watching two or three television programs simultaneously.

CASE 6.4 ► FROM THE INSIDE: Flight of Ideas

Here is an example of a flight of ideas, which a man wrote in his diary during a manic episode:

I have to choose my words very carefully. For what I am doing is, I believe, something which has not very often been attempted (BEELZEBUB ON BED in form of blue fly). It is to think at precisely the same point in the space-time continuum by both methods of thought (Coughing, running at the nose, bottom of feet wet) (blue check handkerchief)—inductive and deductive (so hot, have to remove coat and purple pullover query CAESER'S) artistic and rational (itching), negative and positive—in the terminology expounded [previously] . . .

(Custace, 1952, pp. 138–139)

During a manic episode, the person may also be highly distractible and unable to screen out irrelevant details in the environment or in conversations, as evidenced by the parenthetical comment about the blue check handkerchief in Case 6.4. Another symptom of a manic episode is excessive planning of, and participation in, multiple activities. A college student with this symptom might participate in eight time-intensive extracurricular activities, including a theatrical production, a musical performance, a community service group, and a leadership position in a campus political group.

The expansiveness, unwarranted optimism, grandiosity, and poor judgment of a manic episode can lead to the reckless pursuit of pleasurable activities, such as spending sprees or unusual sexual behavior (infidelity or indiscriminate sexual encounters with strangers). These activities often lead to adverse consequences: credit card debt from the spending sprees or sexually transmitted diseases, including HIV, from unprotected sexual encounters.

People who have had a manic episode report afterward that they felt as if their senses were sharper during the episode—that their ability to smell or hear was better. Unfortunately, during a manic episode, individuals often don't recognize that they're ill; this was the case with Jamison, who, for many years, resisted getting treatment.

Typically, a manic episode begins suddenly, with symptoms escalating rapidly over a few days; symptoms can last from a few weeks to several months. Compared to an MDE, a manic episode is briefer and ends more abruptly.

Mixed Episode

Another building block for diagnosing bipolar disorders is a *mixed episode*—an episode of mood disturbance characterized by symptoms of both manic *and* major depressive episodes. Prominent symptoms usually include:

- agitation,
- insomnia,
- appetite dysregulation,
- psychotic features, and
- suicidal thinking.

Jack Sullivan/Alamy

During a manic episode, individuals may gamble excessively or act antisocially, behaviors they would never otherwise do. Similarly, people who are otherwise very ethical may behave unethically during a manic episode.

Flight of ideas

Thoughts that race faster than they can be said.

During a hypomanic episode, which is less intense than a manic episode, an individual may go on spending sprees or make foolish investments.

A mixed episode may last weeks to months, at which point all or some of the symptoms may disappear. Alternatively, a mixed episode may evolve into an MDE or, less often, into a manic episode. Mixed episodes are more common in young people and those over 60 years old, and they are more common among males than females (American Psychiatric Association, 2000).

Hypomanic Episode

The last building block for diagnosing bipolar disorders is a *hypomanic episode*, which is a distinct period of persistent and pervasive elated, irritable, or euphoric mood that is less distressing than mania and doesn't impair functioning, but it is clearly different from the individual's nondepressed state. Hypomania does not have psychotic features, nor does it require hospitalization; hypomania rarely includes the flight of ideas that bedevils someone in the grips of mania (American Psychiatric Association, 2000). In contrast to the grandiose thoughts people have about themselves during manic episodes, during hypomanic episodes people are uncritically self-confident but not grandiose. When hypomanic, some people may be more efficient and creative than they typically are (American Psychiatric Association, 2000). During a hypomanic episode, people may tend to talk loudly and rapidly, but, unlike what happens when people are manic, it is possible to interrupt them.

Two key features distinguish manic and hypomanic episodes:

1. Hypomania does not impair functioning; mania does.
2. Symptoms of a hypomanic episode must last for a minimum of 4 days, compared to 1 week for a manic episode.

Some research suggests that the 4-day minimum duration for a hypomanic episode specified in DSM-IV-TR may be too restrictive and that 2 days may be a more appropriate criterion for duration (Akiskal, 2003; Angst et al., 2003). Like a manic episode, a hypomanic episode begins suddenly; symptoms rapidly escalate during the first day or two but can last several weeks to months.

Kay Jamison remembered her episodes of hypomania fondly, which made it all the harder for her to continue to take the medication that evened out her moods:

I tend to compare my current [medicated] self with the best I have been, which is when I have been mildly manic . . . most productive, most intense, most outgoing and effervescent. In short, for myself, I am a hard act to follow.

(1995, p. 92)

The Two Types of Bipolar Disorder

The presence of different types of mood episodes—different building blocks—leads to different diagnoses. According to DSM-IV-TR, there are two types of bipolar disorder: bipolar I disorder and bipolar II disorder. Another disorder—cyclothymia (to be discussed later)—is characterized by symptoms of hypomania and depression that do not meet the criteria for the two types of bipolar disorder we are about to discuss.

Bipolar I Versus Bipolar II Disorder

The presence of manic *symptoms*—but not a manic episode—is the common element of the two types of bipolar disorder. The types differ in the severity of the manic symptoms. To receive the diagnosis of the more severe *bipolar I disorder*, a person must have a manic or mixed episode; an MDE may also occur with bipolar I. Thus, just as an MDE automatically leads to a diagnosis of MDD, having a mixed or manic episode automatically leads to a diagnosis of bipolar I. In contrast, to be diagnosed with *bipolar II disorder*, a person must alternate

Table 6.8 ▶ DSM-IV-TR Diagnostic Criteria for Bipolar II Disorder

- A.** Presence (or history) of one or more major depressive episodes.
- B.** Presence (or history) of at least one hypomanic episode.
- C.** There has never been a manic episode or a mixed episode.
- D.** The mood symptoms in Criteria A and B are not better accounted for by schizoaffective disorder and are not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified [all discussed in Chapter 12].
- E.** The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Source: Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision, (Copyright 2002) American Psychiatric Association.

between hypomanic episodes and MDEs (see Table 6.8); bipolar II can be thought of as less severe because of the absence of manic episodes. Table 6.9 provides additional facts about bipolar disorders.

Both types of bipolar disorder can include **rapid cycling** of moods, defined as having four or more episodes that meet the criteria for any type of mood episode within 1 year (American Psychiatric Association, 2000). Rapid cycling is more common with bipolar II disorder and in women (Papadimitriou et al., 2005). Unfortunately, rapid cycling of either type of bipolar disorder is associated with more difficulty in finding an effective treatment (Ozcan, Shivakumar, & Suppes, 2006). The specifiers for MDD—features of psychosis, catatonia, melancholia, atypical, and postpartum onset—also apply to the MDEs experienced by people diagnosed with bipolar disorders.

Even for those who do not have rapid cycling, changes in the sleep-wake cycle (such as sleep deprivation and moving across time zones) can trigger or intensify a manic, mixed, or hypomanic episode (Johnson & Roberts, 1995; Leibenluft, 2008; Leibenluft et al., 1996). Moreover, those who are most likely to relapse have mood symptoms that do not completely clear up after a mood episode ends (although the symptoms do diminish enough that the criteria for a mood episode are no longer met; Judd et al., 2008).

As with depression, people of different races and ethnicities are equally likely to be afflicted with bipolar disorders (American Psychiatric Association, 2000). Some mental health clinicians, however, tend to diagnose schizophrenia instead of a bipolar disorder when evaluating black individuals (Neighbors et al., 2003).

From Jamison's descriptions, some of her experiences, such as those at the faculty garden party, appear to have been manic episodes. Because she had at least one manic episode, Jamison would be diagnosed with bipolar I disorder. The tentative diagnosis of MDD proposed earlier in the chapter would be changed to bipolar disorder in light of Jamison's history of at least one manic episode.

Bipolar Disorder and Creativity?

Are people with bipolar disorder more creative? Jamison and her colleagues (Goodwin & Jamison, 1990; Jamison, 1989; Jamison et al., 1980; see also Hershman & Lieb, 1988, 1998) have argued that a “loosening” of thought that occurs during a manic episode enhances creativity. However, studies supporting this argument often have had methodological problems. For instance, some studies have focused on historical figures (such as famous composers and writers), but these “participants” with bipolar disorder were selected *because*

Rapid cycling (of moods)

Having four or more episodes that meet the criteria for any type of mood episode within 1 year.

Table 6.9 ▶ Bipolar Disorders Facts at a Glance

Prevalence
<ul style="list-style-type: none"> Between 0.4% and 1.6% of American suffer from bipolar I disorder. Approximately 0.5–1% of Americans will develop bipolar II disorder in their lifetimes (Merikangas et al., 2007). Approximately 10–15% of adolescents who are diagnosed as having recurrent MDEs will go on to develop bipolar I disorder.
Onset
<ul style="list-style-type: none"> Both men and women begin to have symptoms of bipolar I disorder by the age of 20, on average, although the symptoms do not necessarily include full-blown manic attacks.
Comorbidity
<ul style="list-style-type: none"> Up to 65% of those with any bipolar disorder are also diagnosed with another Axis I disorder (McElroy et al., 2001), such as anorexia nervosa, bulimia nervosa, attention deficit hyperactivity disorder, panic disorder, or social phobia (American Psychiatric Association, 2000; Merikangas et al., 2007). Around 60% of people with a bipolar disorder also have substance-related problems (Regier et al., 1990).
Course
<ul style="list-style-type: none"> Individuals who have had one manic episode have a 90% chance of having at least one further manic episode. People who have bipolar II disorder are less likely to develop psychotic symptoms during an MDE than are people with bipolar I disorder. Bipolar II disorder typically has a more chronic, though less severe, course than bipolar I disorder (Judd et al., 2003). Approximately 60–70% of those with either type of bipolar disorder will have an MDE after a manic or hypomanic episode. People with either type of bipolar disorder have MDEs that are more severe and lead to more lost work days than do people with depressive disorders (Kessler et al., 2006).
Gender Differences
<ul style="list-style-type: none"> Almost half of men with bipolar I disorder have their first full-blown manic episode by age 25; in contrast, only one third of women have their first manic episode by that age (Kennedy et al., 2005). Bipolar I disorder is equally common among males and females, but bipolar II disorder is more common among females than among males. In males, the number of manic episodes (or hypomanic in the case of bipolar II disorder) often equals or exceeds the number of MDEs, whereas in women, MDEs predominate. For women, having a bipolar disorder boosts the risk of developing mood episodes (of any kind) immediately after giving birth. As with depressive episodes, symptoms of any other type of mood episode (manic, hypomanic, or mixed) may get worse premenstrually.

they had obvious creative genius; they were not randomly selected from a general population of people with bipolar disorder. Also, some of the studies have relied on biographical accounts of the family and friends of such creative people; such sources and the biographers typically are not mental health clinicians and so they may be less able to judge whether the creative person's behavior meets the criteria for a disorder. In an effort to circumvent such problems, some studies

have examined the relationship between bipolar disorder and creativity by asking supposedly “blind” raters to assess various creative works, which included those of famous creative geniuses. However, the raters may have known whose works they were assessing, which would have biased their ratings (Richards et al., 1988; Rothenberg, 2001).

In contrast to the view of Jamison and her colleagues that mania enhances creativity, others have claimed that mental illness may be independent of creativity (Richards et al., 1988; Rothenberg, 2001). One study compared the creativity of people with bipolar disorder to the creativity of: (1) people who had a psychological disorder that was *not* a mood disorder; and, (2) people who did not have any psychological disorder. Bipolar disorder did not confer a creative advantage (Richards et al., 1988).

Cyclothymic Disorder

Just as dysthymia is a more chronic but less intense version of MDD, *cyclothymia* is a more chronic but less intense version of bipolar II disorder. The main feature of **cyclothymic disorder** is a chronic, fluctuating mood disturbance with numerous periods of hypomanic symptoms and numerous periods of depressive symptoms that do not meet the criteria for an MDE (see Table 6.10). Cyclothymia has a lifetime prevalence of 0.4–1.0% and affects men and women equally often (American Psychiatric Association, 2000). Some people may function particularly well during the hypomanic periods of cyclothymic disorder, but be impaired during depressive periods; this diagnosis is given only if the individual’s depressed mood leads him or her to be distressed or impaired. Thus, someone with cyclothymic disorder may feel really upbeat and energetic when hypomanic and begin several projects at work or volunteer to complete projects ahead of schedule. However, when having symptoms of depression, he or she may have some difficulty concentrating or mustering the energy to work on the projects, and so fall behind on the deadlines.

Table 6.10 ▶ DSM-IV-TR Diagnostic Criteria for Cyclothymic Disorder

A. For at least 2 years, the presence of numerous periods with hypomanic symptoms and numerous periods with depressive symptoms that do not meet criteria for a major depressive episode.

Note: In children and adolescents, the duration must be at least 1 year.

B. During the above 2-year period (1 year in children and adolescents), the person has not been without the symptoms in Criterion A for more than 2 months at a time.

C. No major depressive episode, manic episode, or mixed episode has been present during the first 2 years of the disturbance.

Note: After the initial 2 years (1 year in children and adolescents) of cyclothymic disorder, there may be superimposed manic or mixed episodes (in which case both bipolar I disorder and cyclothymic disorder may be diagnosed) or major depressive episodes (in which case both bipolar II disorder and cyclothymic disorder may be diagnosed).

D. The symptoms in Criterion A are not better accounted for by schizoaffective disorder and are not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified [all these disorders are discussed in Chapter 12].

E. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism).

F. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Are people with bipolar disorders more creative? Although actress, author, and screenwriter Carrie Fisher has a bipolar disorder, many people with such a disorder are not exceptionally creative, and many creative people do not have such a disorder. Research suggests that the two variables—the presence of bipolar disorder and creativity—may be unrelated (Rothenberg, 2001).

Cyclothymic disorder

A mood disorder characterized by chronic, fluctuating mood disturbance with numerous periods of hypomanic symptoms and numerous periods of depressive symptoms that do not meet the criteria for an MDE.

Cyclothymia usually unfolds slowly during early adolescence or young adulthood, and it has a chronic course, as Mr. F's history reveals (see Case 6.5). Approximately 15–50% of people with cyclothymia go on to develop some type of bipolar disorder (American Psychiatric Association, 2000).

CASE 6.5 ► FROM THE OUTSIDE: Cyclothymic Disorder

At his girlfriend's insistence, Mr. F., a 27-year-old single man, goes for a psychiatric evaluation. Mr. F. reports that he is excessively energetic, unable to sleep, irritable, and isn't satisfied with the humdrum nature of his work and personal life. He was often dissatisfied and irritable for periods of time ranging from a few days to a few weeks. These periods alternate with longer periods of feeling dejected, hopeless, worn out, and wanting to die; his moods can shift up to 20–30 times each year, and he describes himself as on an "emotional roller-coaster," and has been for as long as he can remember. He twice impulsively tried to commit suicide with alcohol and sleeping pills, although he has never had prominent vegetative symptoms, nor has he had psychotic symptoms.

(Adapted from Frances & Ross, 1996, p. 140)

Figure 6.4

MDE = Major depressive episode

* According to DSM-IV-TR, once this diagnosis is made, the clinician should also note what type of mood episode is current or most recent.

Because Jamison had both MDEs and manic episodes, her symptoms do not meet the criteria for cyclothymic disorder. Figure 6.4 identifies the key mood episodes that are the diagnostic building blocks of the various mood disorders.

Understanding Bipolar Disorders

Manic-depression . . . is an illness that is biological in its origins, yet one that feels psychological in the experience of it; an illness that is unique in conferring advantage and pleasure, yet one that brings in its wake almost unendurable suffering and, not infrequently, suicide.

I am fortunate that I have not died from my illness, fortunate in having received the best medical care available, and fortunate in having the friends, colleagues, and family that I do.

(Jamison, 1995, p. 6)

Kay Jamison made her professional life into a quest to understand mood disorders and why some people develop them. Let's examine what is known about bipolar disorders using the neuropsychosocial approach.

Neurological Factors

As with depressive disorders, both distinctive brain functioning and genetics are associated with bipolar disorders.

Brain Systems

One hint about a neurological factor that may contribute to bipolar disorders is the finding that the amygdala is enlarged in people who have been diagnosed with a bipolar disorder (Altshuler et al., 1998). This finding is pertinent because the amygdala is involved in expressing emotion, as well as regulating mood and accessing emotional memories (LeDoux, 1996). A larger amygdala may be a more emotionally reactive amygdala. Consistent with this idea, researchers have also found that the amygdala is more active in people who

are experiencing a manic episode than it is in a control group of people who are not manic (Altshuler et al., 2005). The more reactive the amygdala, the more readily it triggers strong emotional reactions—and hence the fact that it is especially active during a manic episode makes sense.

Neural Communication

As we've discussed earlier in this chapter and in Chapter 2, imbalances in the levels of certain chemicals in the brain can contribute to psychological disorders. There's reason to believe that serotonin (Goodwin & Jamison, 1990) and norepinephrine play a role in bipolar disorders. For example, treatment with lithium (discussed shortly) not only lowers norepinephrine levels, but also reduces the symptoms of a bipolar disorder (Rosenbaum et al., 2005). As noted in Chapter 2, serotonin is an inhibitory neurotransmitter, and low levels of it are associated with depression (Mundo et al., 2000). However, we've also emphasized that glitches in neural communication contribute to psychological disorders in complex ways; the problem rarely (if ever) is limited to an imbalance of a single substance, but rather typically involves complex interactions among substances. In fact, researchers have also reported that the left frontal lobes of patients with mania produce too much of the excitatory neurotransmitter glutamate (Michael et al., 2003), so at least three neurotransmitters—serotonin, norepinephrine, and glutamate—are involved in bipolar disorders. Thus, changing the level of any one of these substances above is not likely to be sufficient.

Genetics

One day, Jamison and another scientist who does research on mood disorders sat down together, and Jamison drew her family tree: circles represented women, squares represented men, and darkened shapes noted family members who had a mood disorder. Here is what Jamison remembers about this:

I was amazed at how many of my squares and circles were darkened, or darkened with a question mark placed underneath (I knew, for instance, that my great-uncle had spent virtually all of his adult life in an asylum, but I didn't know what his diagnosis had been). Manic-depressive illness occurred repeatedly, throughout the three generations I had knowledge of, on my father's side of the family; asterisks, representing suicide attempts, showed up like a starfield. My mother's side of the family, in comparison, was squeaky clean.

(p. 189)

Jamison's discovery of her paternal relatives' mood disorders mirrors the results of research on the frequency of mood disorders in families: Twin and adoption studies suggest that genes influence who will develop bipolar disorders. If one monozygotic twin has a bipolar disorder, the co-twin has a 40–70% chance of developing the disorder; if one dizygotic twin has the disorder, the co-twin has only about a 5% chance of developing the disorder, which is still over twice the prevalence in the population in general (Fridman et al., 2003; Kieseppä et al., 2004; McGuffin et al., 2003). In general, if you have a first-degree relative who has bipolar disorder, you have a 4–24% risk of developing the disorder (American Psychiatric Association, 2000).

Depressive disorders and bipolar disorders—even though they now are considered distinct disorders—may be different manifestations of the same genetic vulnerability (Akiskal, 1996; Angst, 1998). When a dizygotic twin has a bipolar disorder, the other twin has an 80% chance of developing any mood disorder (MDD, dysthymia, a bipolar disorder, or cyclothymia; Karkowski & Kendler, 1997; McGuffin et al., 2003; Vehmanen, Kaprio, & Loennqvist, 1995). Even so, researchers do not know how specific genes contribute to an inherited vulnerability for mood disorders. But they do know that genes alone cannot account for the development of such disorders—and thus, we next will examine the role that psychological factors play in bipolar disorders.

Psychological Factors: Thoughts and Attributions

Most research on the contribution of psychological factors to bipolar disorders focuses on cognitive distortions and automatic negative thoughts, which not only are common among people with depression but also plague people with a bipolar disorder during MDEs. In fact, research suggests that when depressed, people with either MDD or a bipolar disorder have a similar internal attributional style for negative events (Lyon, Startup, & Bentall, 1999; Scott et al., 2000). Mirroring these results, people with cyclothymia or dysthymia have a similar negative attributional style (Alloy et al., 1999).

In addition, even after a manic episode is completely resolved, up to a third of people may have residual cognitive deficits, ranging from difficulties with attention, learning, and memory to problems with executive functioning (planning and decision making) and problem solving (Martínez-Arán et al., 2000, 2005; Kolar et al., 2006; Rubinstein et al., 2000; Scott et al., 2000; Thompson et al., 2005; Zubietta et al., 2001). Moreover, the more mood episodes a person has, the more severe these deficits tend to be. Researchers propose that the persistent cognitive deficits associated with mania should become part of the diagnostic criteria for bipolar disorders, in addition to criteria on mood-related behaviors (Phillips & Frank, 2006).

Research results have not yet established a cause-and-effect relationship between the cognitive deficits and the mood symptoms of bipolar disorders. For instance, it is possible that having more episodes of mania or depression somehow causes the enduring cognitive deficits. But it is also possible that aspects of their cognitive deficits lead some people to be more likely to have additional mood episodes. Alternatively, it is possible that some other, as yet unidentified, variable leads to both the enduring cognitive deficits and the frequency of mood episodes.

Social Factors: Social and Environmental Stressors

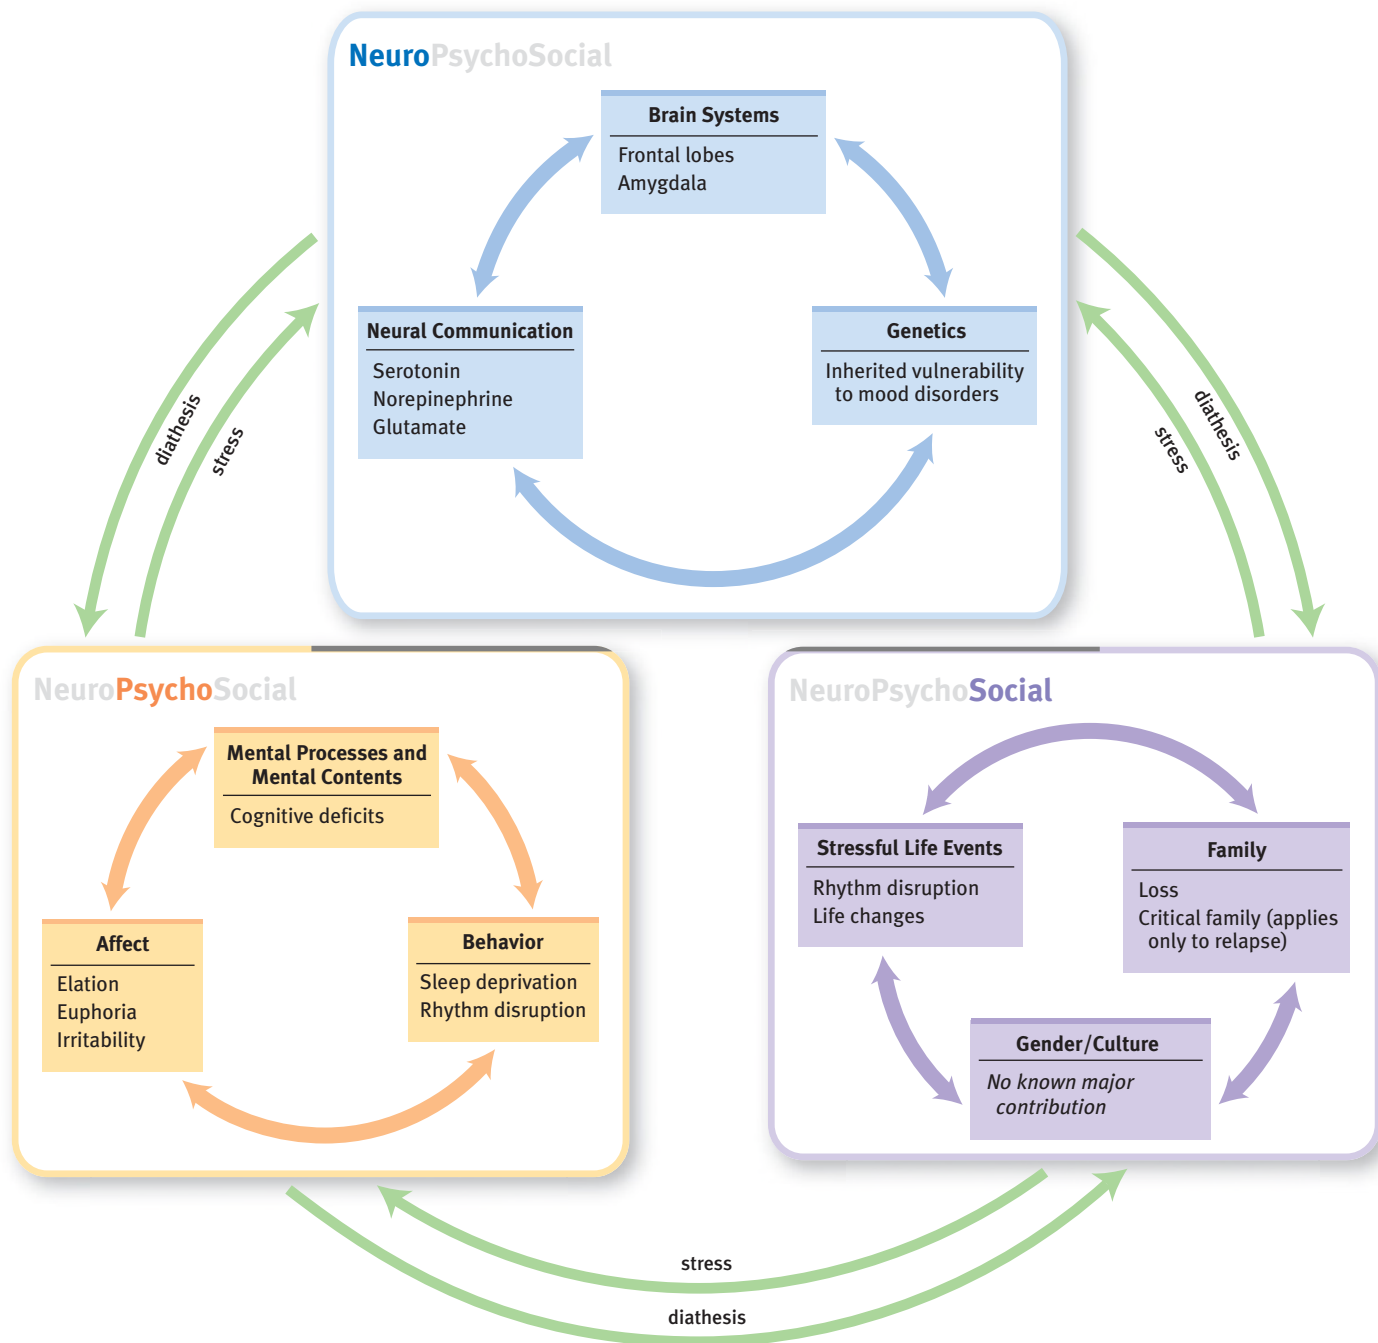

Social factors such as starting a new job or moving to a different city can also affect the course of bipolar disorders (Goodwin & Jamison, 1990; Malkoff-Schwartz et al., 1998). Stress appears to be part of the process that leads to a first episode (Kessing, Agerbo, & Mortensen, 2004); people who develop a bipolar disorder experience significant stressors in their lives before their first episode (Goodwin & Ghaemi, 1998; Tsuchiya, Agerbo, & Mortensen, 2005). Stress can also worsen the course of the disorder (Johnson & Miller, 1997). In addition, stress—in particular, family-related stress—may contribute to relapse; people who live with family members who are critical of them are more likely to relapse than those whose family members are not critical (Honig et al., 1997; Miklowitz et al., 1988).

Social factors can also have indirect effects, as occurs when a new job disrupts a person's sleep pattern, which in turn triggers neurological factors that can lead to a mood episode (American Psychological Association, 2000).

FEEDBACK LOOPS IN ACTION: Bipolar Disorders

Bipolar disorders have a clear genetic and neurological basis, but feedback loops still operate among the neurological, psychological, and social factors associated with these disorders (see Figure 6.5). Consider the effects of sleep deprivation. It may directly or indirectly affect neurological functioning, making the individual more vulnerable to a manic or depressive episode. Moreover, like people with depression, people with a bipolar disorder tend to have an attributional style (psychological factor) that may make them more vulnerable to becoming depressed. In turn, their attributional style may affect how these people interact with others (social factor), such as their responses to problems in relationships. Even after a mood episode is over, residual problems with cognitive functioning—which affects problem solving, planning, or decision making—can adversely influence the work and social life of a person with a bipolar disorder.

Figure 6.5

Note: The factors related to depressive disorders also apply to depressive episodes with bipolar disorders.

6.5 ► Feedback Loops in Action: Bipolar Disorders

We can now understand Jamison's bipolar disorder as arising from a confluence of neuropsychosocial factors and feedback loops. Her family history provided a strong genetic component to her illness, which has a clear neurological basis (neurological factors). Her struggle against recognizing that she had an illness

(psychological factors) meant that she didn't do as good a job as she could have done in protecting herself from overwork (social factor), making her more vulnerable to a mood episode.

Treating Bipolar Disorders

As with depressive disorders, treatment for bipolar disorders can directly target any of the three types of factors—neurological, psychological, and social. Keep in mind, though, that the effects of any successful treatment extend to all the types of factors. Jamison describes the subtle ways that feedback loops operated on her disorder and treatment:

My temperament, moods, and illness clearly, and deeply, affected the relationships I had with others and the fabric of my work. But my moods were themselves powerfully shaped by the same relationships and work. The challenge was in learning to understand the complexity of this mutual beholdenness and in learning to distinguish the roles of lithium, will, and insight in getting well and in leading a meaningful life. It was the task and gift of psychotherapy.

(1995, p. 88)

Targeting Neurological Factors: Medication

People diagnosed with a bipolar disorder usually take some type of **mood stabilizer**—a medication that minimizes mood swings—for the rest of their lives. (The term *mood stabilizer* is sometimes used more broadly to include medications that decrease impulsive behavior and violent aggression.) Mood stabilizers can reduce recurrences of both manic and depressive episodes (Arana & Rosenbaum, 2000). The oldest mood stabilizer is **lithium**; technically the medication is called *lithium carbonate*, a type of salt. Jamison describes her response to the drug: “I took [lithium] faithfully and found that life was a much stabler and more predictable place than I had ever reckoned. My moods were still intense and my temperament rather quick to the boil, but I could make plans with far more certainty and the periods of absolute blackness were fewer and less extreme” (1995, p. 153). Lithium apparently affects several different neurotransmitters (Jope, 1999; Lenox & Hahn, 2000) and thereby alters the inner workings of neurons (Friedrich, 2005). Too high a dose of lithium can produce severe side effects, including coordination problems, vomiting, muscular weakness, blurred vision, and ringing in the ears; thus, patients must have their blood levels of lithium checked regularly to ensure that they are taking an appropriate dosage (Arana & Rosenbaum, 2000).

However, up to half of patients taking lithium either cannot tolerate the side effects or do not show significant improvement, especially patients who have mixed episodes or rapid cycling (Burgess et al., 2001; Keck & McElroy, 2003; Montgomery et al., 2001; Soares, 2000). In such cases, other mood stabilizers may be effective in preventing extreme mood shifts, especially recurring manic episodes. These include antiepileptic medications (also called *anticonvulsants*) such as *divalproex* (Depakote), *carbamazepine* (Tegretol), *lamotrigine* (Lamictal), and *gabapentin* (Neurontin).

Some people with bipolar disorders stop taking mood stabilizers, not necessarily because of the common side effects (such as thirst, frequent urination, and diarrhea), but because the medication does what it's supposed to do—evens out their moods (Arana & Rosenbaum, 2000; Rosa et al., 2007). Some of these people report that they miss aspects of their manic episodes and feel that the medication blunts their emotions.

Mood stabilizers aren't the only medications given for bipolar disorders. Patients with a bipolar disorder may be given antidepressant medication for depression, but such medications can induce mania and so should be taken along with a mood stabilizer; in addition, patients with a bipolar disorder who take antidepressant

Mood stabilizer

A category of medication that minimizes mood swings.

Lithium

The oldest mood stabilizer; it is administered as a salt.

medication should take it for as brief a period as possible (Rosenbaum et al., 2005). Antidepressants may not be prescribed for people with rapid cycling, however, because these drugs can exacerbate the cycling (Schneck et al., 2008). For a manic episode, an antipsychotic medication such as *olanzapine* (Zyprexa) or *aripiprazole* (Ablify), or a high dose of a benzodiazepine may be given (Arana & Rosenbaum, 2000; Keck et al., 2009).

Despite the number of medications available to treat bipolar disorders, mood episodes still recur; in one study, half of the participants developed a subsequent mood episode within 2 years of recovery from an earlier episode (Perlis, Ostacher, et al., 2006).

Targeting Psychological Factors: Thoughts, Moods, and Relapse Prevention

Medication can be an effective component of treatment for bipolar disorders, but often it isn't the only component. Treatment that targets psychological factors focuses on helping patients develop patterns of thought and behavior that minimize the risk of relapse (Fava et al., 2001; Jones, 2004; Scott & Gutierrez, 2004), including consistently taking medication. CBT can help patients to stick with their medication schedules, develop better sleeping strategies, and recognize early signs of mood episodes, such as needing less sleep (Ball et al.,

Figure 6.6

Daily Log of Social Rhythms															
Directions: • Write the ideal target time you would like to do these daily activities. • Record the time you actually did the activity each day. • Record the people involved in the activity: 0=Alone; 1=Others present; 2=Others actively involved; 3=Others very stimulating

Out of bed															
First contact with other person															
Start work/school/volunteer/family care															
Dinner															
To bed															
Rate MOOD each day from -5 to +5 -5=very depressed +5=very elated															

6.6 ▶ Assessing Social Rhythms One component of interpersonal and social rhythm therapy helps patients determine what types of social rhythm disruptions are likely to trigger a mood episode. A daily social rhythm log, like this one, can help patients identify the disruptions that increase their mood symptoms. Once they identify these disruptions, they can develop strategies to minimize them.

Source: Frank, Gonzalez, & Fagiolini, 2006, p. 984, Figure 2. For more information see the Permissions section.

2006; Brondolo & Mas, 2001; Frank et al., 2005; Miklowitz, 2008; Miklowitz et al., 2007).

Targeting Social Factors: Interacting with Others

Treatments that target social factors are designed to help patients minimize disruptions in their social patterns and develop strategies for better social interactions (Lam et al., 2000). One such treatment *interpersonal and social rhythm therapy* (IPSRT), was adapted from interpersonal therapy specifically for people with bipolar disorders (Frank et al., 1999) to address social factors that contribute toward relapse of mania. As in IPT, IPSRT sessions focus on identifying themes of social stressors, such as a relationship conflict (a *role dispute* in IPT; see Chapter 4) that arises because the partners have different expectations of the relationship. Treatment can then focus on developing effective ways for the patient to minimize such social stressors. In addition, IPSRT focuses on the timing of events (such as arranging weekend activities so that the patient wakes up at the same time each morning and goes to sleep at the same time each night—weekend and weekday), on increasing overall regularity in daily life (such as having meals at relatively fixed times during the day; see Figure 6.6), and helping the patient *want* to maintain regularity. IPSRT plus medication is more effective than medication alone (Frank et al., 1999; Miklowitz, 2008; Miklowitz et al., 2007).

Other treatments that target social factors focus on the family, educating family members about bipolar disorder and providing emergency counseling during crises (Miklowitz et al., 2000, 2003, 2007). Also, family therapy that reduces the critical behavior of family members can reduce relapses (Honig et al., 1997). Another treatment with a social focus is group therapy or a self-help group, either of which can decrease the sense of isolation or shame that people with bipolar disorders may experience; group members support each other as they try to make positive changes.

FEEDBACK LOOPS IN TREATMENT: Bipolar Disorder

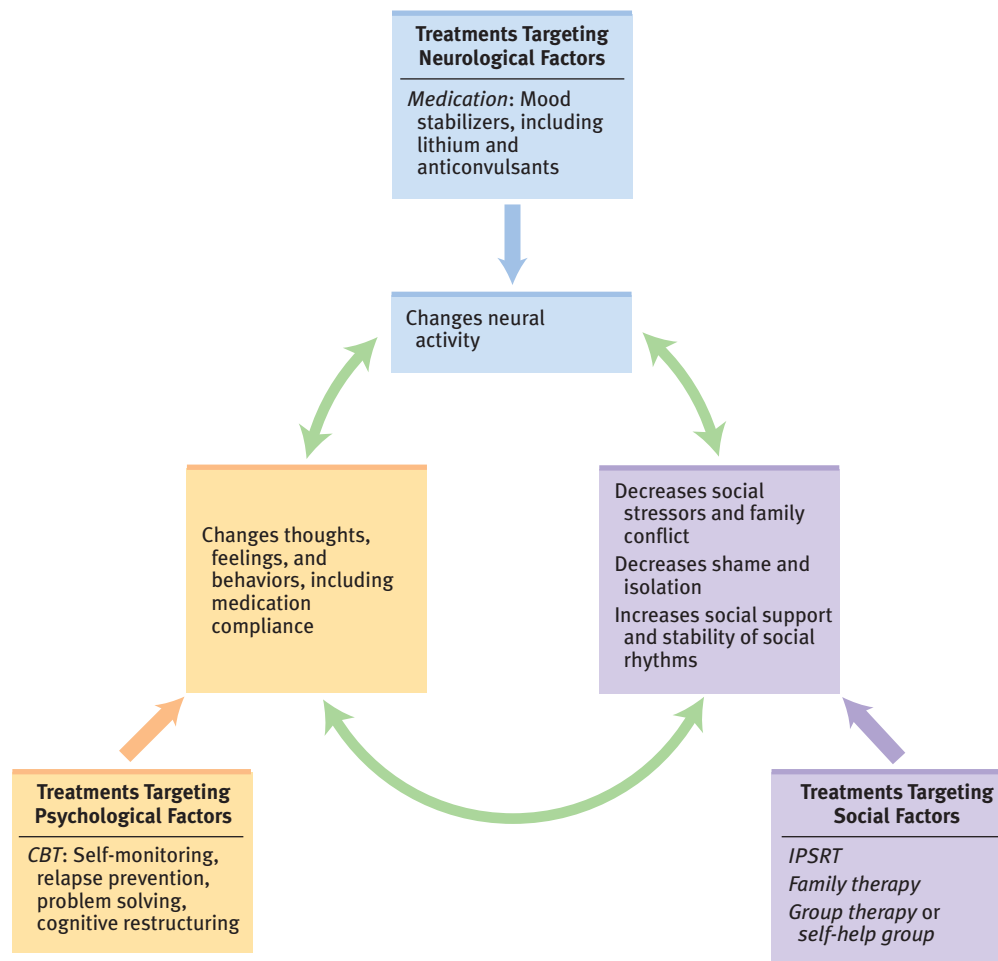

Both Jamison and her psychiatrist understood that treatment could affect multiple factors:

No pill can help me deal with the problem of not wanting to take pills; likewise, no amount of psychotherapy alone can prevent my manias and depressions. I need both. It is an odd thing, owing life to pills, one's own quirks and tenacities, and this unique, strange, and ultimately profound relationship called psychotherapy.

(1995, p. 89)

We have seen that successful treatments for bipolar disorders can address multiple factors—for example, CBT can result in more consistent medication use and IPSRT can reduce triggers of relapse. Successful treatment can also affect interpersonal relationships. As patients begin to recover from a bipolar disorder, they interact differently with others, develop a more regular schedule, and come to view themselves differently. They change the attributions they make about events and even change how reliably they take medication for the disorder. Figure 6.7 summarizes the feedback loops involved in the treatment of bipolar disorders.

Jamison's treatment involved interactions among the factors: Her therapy helped her to recognize and accept her illness and encouraged her to take care of herself more appropriately (psychological and social factors), including sticking with a daily regimen of lithium (neurological factor). Furthermore, the successful lithium treatment allowed her to have better relationships with others (social factor), which led to a positive change in how she saw herself (psychological factor).

Figure 6.7

Note: Treatments for depressive disorders may also be used to treat depressive symptoms in people with bipolar disorders.

6.7 ► Feedback Loops in Treating Bipolar Disorders

Key Concepts and Facts About Bipolar Disorders

- The four building blocks for diagnosing bipolar disorders are major depressive episode (MDE), manic episode, mixed episode, and hypomanic episode. Symptoms of a manic episode include grandiosity, pressured speech, flight of ideas, distractibility, poor judgment, decreased need for sleep, and psychomotor agitation. A mixed episode is characterized by symptoms of both an MDE and a manic episode and may include psychotic features and suicidal thinking. A hypomanic episode involves mood that is persistently elated, irritable, or euphoric; unlike other mood episodes, hypomanic episodes do not impair functioning.
- There are two types of bipolar disorder. Bipolar I disorder—usually more severe—requires only a manic or mixed episode; an MDE may occur but is not necessary for this diagnosis. Bipolar II disorder requires alternating hypomanic episodes and MDEs and no history of manic or mixed episodes. Both disorders may involve rapid cycling. Cyclothymic disorder is a more chronic but less intense version of bipolar II disorder.
- Neurological factors that are associated with bipolar disorders include an enlarged and more active amygdala. Norepinephrine, serotonin, and glutamate are also involved. Bipolar disorders are influenced by genetic factors, which may influence mood disorders in general.
- Psychological factors that are associated with bipolar disorders include the cognitive distortions and negative thinking associated with depression. Moreover, some people with bipolar I disorder may have residual cognitive deficits after a manic episode is over.

continued on next page

- Social factors that are associated with bipolar disorders include disruptive life changes and social and environmental stressors. The different factors create feedback loops that can lead to a bipolar disorder or make the patient more likely to relapse.
- Treatments that target neurological factors include lithium and anticonvulsants, which act as mood stabilizers. When manic, patients may receive an antipsychotic medication or a benzodiazepine. Patients with a bipolar disorder who have MDEs may receive an antidepressant along with a mood stabilizer.
- Treatment that targets psychological factors—particularly CBT—helps patients recognize warning signs of mood episodes, develop better sleeping strategies, and, when appropriate, stay on medication.
- Treatments that target social factors include:
 - interpersonal and social rhythm therapy (IPSRT), which can increase the regularity of daily events and decrease social stressors;

- family therapy, which is designed to educate family members about bipolar disorder, improve positive communication, and decrease criticism by family members; and
- group therapy or a self-help group, which is intended to decrease shame and isolation.

Making a Diagnosis

- Reread Case 6.4 about the person with flight of ideas, and determine whether or not the man's symptoms meet the criteria for a bipolar disorder, and if so, which type of bipolar disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 6.5 about Mr. F., and determine whether or not his symptoms meet the criteria for cyclothymic disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Past research suggested that suicide rates peak in the spring for both men and women, with another peak in the autumn for women (Barracough & White, 1978a, 1978b; Meares et al., 1981). However, more recent research suggests that such a relationship may be weakening over time (Hakko, Räsänen, & Tiihonen, 1998; Jessen, Steffensen, & Jensen, 1998; Parker et al., 2001; Rihmer et al., 1998; Yip, Callahan, & Yuen, 2000; Yip, Chao, & Ho, 1998; Yip, Yang, & Qin, 2006), perhaps because the effects of seasonal differences are minimized by modern artificial environments (Simkins et al., 2003).

Craig Tuttle/Corbis

Suicide

On more than one occasion, Kay Jamison seriously contemplated suicide. One day, when deeply depressed, she did more than think about it—she attempted suicide. Here she describes her motivation:

I could not stand the pain any longer, could not abide the bone-weary and tiresome person I had become, and felt that I could not continue to be responsible for the turmoil I was inflicting upon my friends and family. In a perverse linking with my mind I thought that . . . I was doing the only fair thing for the people I cared about; it was also the only sensible thing to do for myself. One would put an animal to death for far less suffering. (Jamison, 1995, p. 115)

When Jamison attempted suicide, she was already receiving treatment for her disorder; in contrast, a majority of people who die by suicide have an untreated mental disorder, most commonly depression. Fortunately, Jamison's attempt was foiled. She later describes being grateful that she continued living. The hopelessness that she had felt went away, and she was able to enjoy life again.

Suicidal Thoughts and Suicide Risks

In the United States and Canada, suicide is ranked 11th among causes of death (McIntosh, 2003; Statistics Canada, 2005). Approximately 32,000 people die by suicide each year in the United States (Centers for Disease Control and Prevention [CDC], 2005), which constitutes about 1% of all deaths per year (McIntosh, 2003). Worldwide, suicide is the second most frequent cause of death among women under 45 years old (tuberculosis ranks first), and it is the fourth most frequent cause among men under 45 (after road accidents, tuberculosis, and violence; WHO, 1999). Table 6.11 lists more facts about suicide.

Thinking About, Planning, and Attempting Suicide

When suffering from a mood disorder, people may have thoughts of death or thoughts about committing suicide, known as **suicidal ideation** (Rihmer, 2007). But suicidal ideation does not necessarily indicate the presence of a psychological disorder or an actual suicide risk. Approximately 10–18% of the general population—including

Suicidal ideation
Thoughts of suicide.

Table 6.11 ▶ Suicide Facts at a Glance**Prevalence**

- Approximately 1.3% of all deaths in the United States are considered to be suicides—over 32,000 people annually (CDC, 2005).
- Worldwide, the elderly (65 and older) are three times as likely to commit suicide as are those under 25 years old (WHO, 1999).
- In the United States, suicide is most likely to occur among the elderly, particularly white men; young people (under 26) are the next most likely to commit suicide (CDC, 2005; Miniño et al., 2002; CDC, 2000).
- From 1950 to 1995, worldwide suicide rates increased by 60%, particularly among young men (WHO, 1999), making it the third leading cause of death for teenagers, particularly males (Waters, 2000).

Gender Differences

- Worldwide, women are more likely to attempt suicide than are men (Nock et al., 2008).
- In the United States, although women are more likely to attempt suicide, men are four times more likely to die from an attempt (CDC, 2005).

Cultural Differences

- Hanging is the most common method of suicide worldwide, but guns are the most common method in the United States (particularly among men), undoubtedly because access to them is easier than in other countries (De Leo, 2002a; Moscicki, 1995; Romero & Wintemute, 2002).
- Internationally, Eastern European countries, as a region, have the highest rates of suicide; examples are Belarus (41.5 per 100,000) and Lithuania (51.6 per 100,000). Latin American countries tend to have the lowest rates; examples are Paraguay (4.2 per 100,000) and Colombia (4.5 per 100,000) (WHO, 2002).

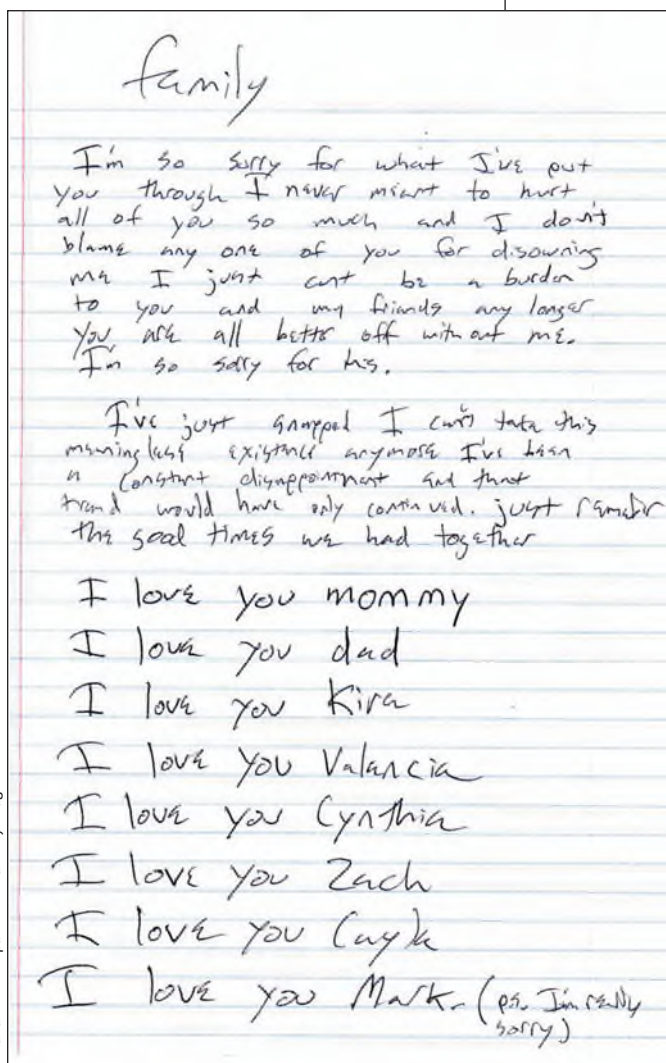

both those with and without disorders—has at some point had suicidal thoughts (Weissman, Bland, et al., 1999). One study found that 6% of people who were healthy and had never been depressed occasionally thought about suicide (Farmer et al., 2001). Suicidal thoughts may range from believing that others would be better off if the person were dead (which Jamison had) to vague ideas of dying by suicide to specific plans to commit suicide.

Approximately 30% of those who have thoughts of suicide have also conceived of a plan (Kessler, Borges, & Walters, 1999). Even having a plan, though, does not by itself indicate that an individual is at risk for suicide. One person with a specific plan to commit suicide may not actually attempt it, whereas another person who had not previously had a serious intention or plan to die by suicide may do so (Kessler, Borges, & Walters, 1999). There are, however, certain behaviors that can suggest serious suicidal intent and can serve as warning signs (Packman et al., 2004):

- giving away possessions,
- saying goodbye to friends or family,
- talking about death or suicide generally or about specific plans to commit suicide,
- making threats of suicide, and
- rehearsing a plan for suicide.

Unfortunately, not everyone who plans or is about to commit suicide displays warning signs.

For some people, suicidal thoughts or plans turn into actions. Certain methods of suicide are more lethal than others, and the more lethal the method, the more likely it is that the suicide attempt will result in death or serious medical problems. For instance, shooting, hanging or jumping from a high place are more lethal than

A body of research examines suicide notes to evaluate what leads some people to try to kill themselves. Any conclusions drawn from such data, however, are limited. Fewer than 40% of the people who commit suicide leave notes, and there may be important differences between those who leave notes and those who don't (Leenaars, 1988; O'Connor, Sheeby & O'Connor, 1999). Moreover, suicide notes are subject to various self-report biases, including the desire to leave a particular impression and to elicit a particular reaction from the readers (Leenaars, 2003).

taking pills or cutting a vein. In the latter situations, the individual often has at least a few minutes to seek help after having acted. Some people may be very ambivalent about suicide and so may attempt suicide with a less lethal method or try to ensure that they are found by others before any lasting damage is done. Unfortunately, these suicide attempts may still end in death because the help the individuals had anticipated did not materialize. Other people who attempt suicide do not appear to be ambivalent; they may or may not display warning signs, but will follow through unless someone or something intervenes (Maris, 2002). One suggestion for DSM-V is that a sixth axis be added for the evaluation of a patient's suicidal risk, just as clinicians and researchers evaluate a patient's level of functioning on Axis V (see Chapter 3) (Oquendo et al., 2008).

Not all acts associated with suicide—such as certain types of skin cutting—are, in fact, suicide attempts. Such deliberate self-harming is usually potentially less lethal and is sometimes referred to as *para-suicidal behavior*. People may harm themselves without any suicidal impulse because they feel numb, or because such self-harming behaviors allow them to “feel something” (Linehan, 1981). Alternatively, some people deliberately harm themselves to elicit particular reactions from others. Parasuicidal behavior is discussed in more detail in Chapter 13.

Risk and Protective Factors for Suicide

The risk of suicide is higher for people who have a psychological disorder—whether officially diagnosed or not—than for those who do not have a disorder. The three most common types of disorders among those who commit suicide are (Brown et al., 2000; Duberstein & Conwell, 1997; Isometsä, 2000; Moscicki, 2001):

- major depressive disorder (50%),
- personality disorders (40%), and
- substance-related disorders (up to 50% of those who commit suicide are intoxicated by alcohol at the time of their death).

People who commit suicide may have more than one of these disorders.

Substance use or abuse plays a pivotal role in many suicide attempts because drugs and alcohol can cloud an individual's judgment and ability to reason. Also, as we'll see in Chapter 9, some substances, such as alcohol, are depressants: They depress the central nervous system and can lead to depressed mood (Rosenbaum et al., 2005). If someone is already depressed and drinks to “take away the pain,” he or she may momentarily feel somewhat better when the blood alcohol level reaches a certain point, but soon thereafter his or her mood will be even worse than before drinking.

A history of being impulsive is another significant risk factor for suicide (Sanchez, 2001). Impulsive people may not exhibit warning signs of serious suicidal intent.

Beyond the presence of specific psychological disorders or impulsivity, another strong predictor of completed suicide is a history of past suicide attempts (Elliott et al., 1996; Moscicki, 1997; Oquendo et al., 2007). Specifically, people who have made serious attempts are more likely subsequently to die by suicide than are those who have made less serious attempts (Ivarsson et al., 1998; Krupinski et al., 1998; Stephens, Richard, & McHugh, 1999). Additional risk factors are listed in Table 6.12. Those at risk may benefit from early evaluation and treatment.

One group at higher risk for suicide is gays and lesbians, particularly during adolescence (Ramafedi, 1999). The increased risk, however, stems primarily from the social exclusion and discrimination experienced by these individuals (Igartua, Gill, & Montoro, 2003). Among homosexuals, suicide is most likely during the

Table 6.12 ▶ Risk and Protective Factors for Suicide**Risk Factors**

- Mental disorder associated with suicidal behavior (depression, schizophrenia, substance abuse, or personality disorder)
- Feeling hopeless
- Being male (in the United States)
- Prior suicidal behavior (suicide threats, suicide attempts)
- Specific behaviors that suggest suicide planning (giving away possessions, saying goodbye to friends, talking about death or suicide, talking about specific plans to commit suicide, rehearsing a suicidal act, and/or accumulating medications)
- Family history of suicidal behavior
- Chronic impulsivity or aggression and low stress tolerance
- Poor coping and problem-solving skills
- Poor judgment and rigid, distorted thinking
- Major life stressors (physical or sexual assault, threats against life, diagnosis of serious medical problem, dissolution of a significant relationship, or sexual identity issues)
- Breakdown of support systems or social isolation
- Changes in mental status (acute deterioration in mental functioning, onset of major mental illness, extreme anxiety, paranoia, or severe depression)
- Unsatisfying relationship history (never married, separated, divorced, or lack of significant relationships)
- Poor work history (spotty work history or chronic unemployment)
- Childhood abuse
- History of violent behavior

Protective Factors

- Being married (or having a significant relationship)
- Employed or involved in a structured program (educational or vocational training program)
- Presence of a support system (family, friends, church, and/or social clubs)
- Having children who are under 18 years of age
- Constructive use of leisure time (enjoyable activities)
- General purpose for living
- Involved in mental health treatment
- Effective problem-solving skills

Source: Adapted from Sánchez, 2001, Appendix A.

period when disclosing their homosexuality to immediate family members (Igartua, Gill, & Montoro, 2003).

Despite such risks, most people who are depressed or have thoughts of suicide do not actually try to kill themselves. Even when in the blackest suicidal despair, specific factors can lessen the risk of a suicide attempt: receiving support from family and friends, holding religious or cultural beliefs that discourage suicide, and getting prompt and appropriate treatment for any depression or substance abuse. Additional protective factors are listed in Table 6.12.

Understanding Suicide

Adding risk factors and subtracting protective factors does not sum up to a definitive probability that a given individual will attempt or complete suicide. Rather, the presence or absence of such factors may create feedback loops over years, the effects of which may or may not culminate in suicide. To understand why some people commit suicide, we now turn to examine relevant neurological, psychological, and social factors and their feedback loops.

Neurological Factors

Because the main risk factors for suicide are associated with depression and impulsivity (as well as past suicide attempts), it's difficult to identify neurological factors that uniquely contribute to suicide (as distinct from factors that contribute to depression and impulsivity). Nevertheless, progress is being made in understanding the neurological factors that contribute to suicide.

Brain Systems and Neural Communication

The frontal lobes may play a key role in suicide, which makes sense because they normally inhibit behavior (and hence disrupted frontal lobe function may be related to impulsivity). In particular, postmortem studies have documented that the frontal lobes of suicide victims have structural abnormalities, such as greater-than-normal neural density (Rajkowska, 1997) and abnormal serotonin receptors (Brunner & Bronisch, 1999).

Many researchers believe that mood disorders in general reflect, at least in part, levels of the neurotransmitter serotonin. Guided by this idea, Biela and colleagues (2005) reported a suggestive trend: They found that people who committed suicide tended to have fewer neurons in the part of the brain that produces serotonin than did people who died of other causes. In addition, researchers have found that people who commit suicide may have had fewer serotonin receptors in their brains (Boldrini et al., 2005). Notably, impulsivity is also associated with low serotonin levels. Given the role of serotonin in impulsivity and aggression (van Heeringen, 2003), its relation to suicide is not surprising: The low levels of serotonin associated with impulsivity may lead a person to act on a thought or emotion that normally would be ignored—and might even facilitate a horrible act of aggression against the self (after all, suicide is murder—the most aggressive of all acts—but directed toward oneself).

Genetics

Suicide seems to “run in families” (Correa et al., 2004), but it is difficult to discern a *specific* role of genes in influencing people to commit suicide. Depression has a genetic component, which may account for the higher rates of suicide among both twins in monozygotic pairs (13%) compared to dizygotic pairs (<1%; Zalsman et al., 2002). Given the apparent role of serotonin in suicide, studying genes related to serotonin is an obvious way to begin to look for genetic contributions to this behavior. However, such investigations have so far been fruitless. Researchers cannot yet identify genes that specifically influence whether a person will commit suicide (Sibille et al., 2004; Stefulj et al., 2004; Tsai et al., 2004).

Psychological Factors: Hopelessness and Impulsivity

Why might individuals think seriously about suicide? The obstacles in their lives may seem to be insurmountable, or suicide may appear to be the only way to end their excruciating emotional pain. However, suicide is a “permanent solution to a temporary problem” (National Depressive and Manic Depressive Association, 2002). When people are in the midst of despair, possible solutions to life's problems may seem elusive, but these feelings typically will lessen or disappear.

A number of the risk factors in Table 6.12 are psychological factors, such as poor coping skills (e.g., behaving impulsively) and poor problem-solving skills (e.g., difficulty identifying obstacles that interfere with meeting goals or failing to develop ways to work around obstacles), distorted and rigid thinking (thought patterns associated with depression), and hopelessness. Hopelessness, with its bleak thoughts of the future, is especially associated with suicide (Beck et al., 1985; Beck et al., 1990). Moreover, to some extent having depressed thoughts is self-perpetuating: When depressed, people are more likely to remember other bad times (Eich, Macaulay, & Lam, 1997). Their thoughts become populated with a string of bad times, from past to present, and onward to the future. They cannot see past their current hopelessness to envision better times or alternative solutions to their problems. And if they

Table 6.13 ► Suicide Rates in Selected Countries

Country or area	Year	Total number of suicides	Suicide rate per 100 000 population			
			Total	Male	Female	Male: female ratio
Argentina	1996	2 245	8.7	14.2	3.9	3.6
Australia	1998	2 633	17.9	28.9	7.0	4.1
Brazil	1995	6 584	6.3	10.3	2.5	4.1

are prone to impulsive behavior, such hopelessness sets them up to be like “an accident just waiting to happen.”

Social Factors: Alienation and Cultural Stress

Suicide rates vary across countries (see Table 6.13; De Leo, 2002a; Vijayakumar et al., 2005; WHO, 1999), which suggests that social and cultural factors affect these rates. In some developing countries, the presence or history of a psychological disorder poses less of a risk for suicide than it does in developed countries (Vijayakumar et al., 2005). Note, however, that social and cultural differences may partly reflect different genetic vulnerabilities to certain risk factors (such as certain psychological disorders). For instance, the residents of one country could have a higher suicide rate, in part, because more people in the country tend to have genes

Cultural norms and customs can influence suicide rates. Among the Yuit Eskimos of St. Lawrence, when someone requests suicide three times, relatives are supposed to help the person kill himself or herself (Leighton & Hughes, 1955). In contrast, among the Tiv of Nigeria, suicide reportedly never occurs (Evans & Farberow, 1988). Such cultural norms about suicide can affect individuals' beliefs and expectations about suicide.

associated with depression. Alternatively, the suicide rates across countries could depend, in part, on the socioeconomic circumstances of citizens; suicide risk increases with economic adversity (Agerbo et al., 2007; Preti, 2003).

How might cultural factors affect suicide rates? The French sociologist Émile Durkheim (1897/1951) formulated a theory after comparing suicide rates in different countries across several periods of time. Durkheim proposed that suicide is more likely when a society is too “individualistic,” and its citizens do not feel enough of a sense of being part of a community or group; that is, they feel alienated from others. Durkheim’s theory may, in part, account for the increasing worldwide suicide rate among young men. That is, young men may feel an increasing sense of alienation and thus become more likely to commit suicide as their society modernizes, and as the social rituals and traditional societal organization that binds young people more closely to their family and community disintegrate. Conversely,

Durkheim proposed that during times of stress, a community may pull together to grapple with the common challenge; when this happens an individual’s sense of belonging to a cohesive group can protect against suicide. Other possible factors that may account for the increased suicide rate among youth are listed in Table 6.14.

Table 6.14 ▶ Possible Causes of the Increased Suicide Rate Among Youth

- Earlier and easier access to alcohol, drugs, and firearms
- Neurological damage to fetuses, from nutritional deficiencies, alcohol, nicotine, or cocaine use in pregnant mothers
- Longer survival of premature babies, with increased vulnerability of their nervous system (as a result of their low birth weight)
- The decrease in the average age of puberty
- The younger age at which depression first occurs
- Actual rates of depression may have increased over time
- More accurate reporting of suicides—thus the actual increase may be smaller than it appears

Source: De Leo, 2002a.

Support for Durkheim’s theory comes from the decrease in suicide rates during good economic times or times of optimism within a culture (Weyerer & Wiedenmann, 1995). For example, in the final years of the Soviet Union (from 1984 to 1988), the suicide rate there decreased by over a third, as its citizens became hopeful about the future (Wasserman & Varnik, 1998).

Another important social factor that influences suicidal behavior is religion. Countries where the citizens are more religious tend to have lower suicide rates than do countries where citizens are less religious. Countries with a large Muslim population are among those with the lowest suicide rates in the world, followed by countries with a large Roman Catholic population; the tenets of both of these religions forbid suicide (De Leo, 2002a; Simpson & Conklin, 1989). Moreover, individuals who are more committed to their religion and more involved with it are less likely to commit suicide, which is consistent with Durkheim’s theory that being an active member of a community decreases alienation, and therefore suicide (Stack 1983; Stack & Wasserman, 1992).

The difference in suicide rates between the sexes provides another example of the ways that culture can contribute to suicide. The ratio of men to women

among those who commit suicide is five to one in some Eastern European countries and up to ten to one in Puerto Rico (WHO, 1999). This pattern of more men than women committing suicide is the rule, but there are exceptions. In India, the suicide rate for men and women is about the same (Mayer & Ziaian, 2002). And in China, particularly in rural areas, women are more likely to commit suicide than men (Ji, Kleinman, & Becker, 2001; Jianlin, 2000; Phillips, Li, & Zhang, 2002). Several explanations have been proposed for China's unique pattern. One is that Chinese women use more lethal methods (such as ingesting insecticides) than non-Chinese women do. In addition, medical facilities are widely scattered in rural China, so even if a woman were found by a friend or family member after she took the poison, there might not be enough time to get her to medical help (Phillips, 2001). Another explanation is that in rural China women are viewed as far inferior to men, leading to a sense of greater frustration and hopelessness among some women (Qin & Mortensen, 2001).

What might explain the gender differences in suicide rates in general? One possibility is that socially related protective factors may be more common or effective among women; that is, women may have better support systems, greater emotional awareness, and may be more willing to seek help (Canetto, 1992; De Leo, 2002a).

FEEDBACK LOOPS IN ACTION: Suicide

Suicide can best be understood as arising from the confluence of neurological, psychological, and social factors. A neurological vulnerability, such as abnormal neurotransmitter functioning, serves as the backdrop. Add to that the psychological factors: depression or feelings of hopelessness, beliefs about suicide, poor coping skills, and perhaps impulsive or violent personality traits. In turn, these factors affect, and are affected by, social and cultural forces—such as economic realities, wars, cultural beliefs and norms about suicide, religion, stressful life events, and social support. The dynamic balance among all these factors will influence the likelihood of an individual's suicidal ideation, plans, and behavior (Sánchez, 2001; Wenzel et al., 2009). Figure 6.8 summarizes the factors that may contribute to suicide, as well as the feedback loops between them.

Preventing Suicide

Suicide prevention efforts can focus on immediate safety or longer-term prevention. Immediate crisis intervention provides resources to help people when they are on the verge of committing suicide; for example, suicide hotlines are available for people who are seriously contemplating killing themselves. Longer-term interventions can help those at increased risk—people who have attempted suicide in the past. Prevention can also encompass treating related disorders, such as substance abuse, which in turn is associated with increased impulsivity and poor judgment. Such prevention efforts can target all three types of factors: neurological, psychological, and social. As we saw with the treatment of mood disorders, successfully changing one type of factor leads to changes in the others.

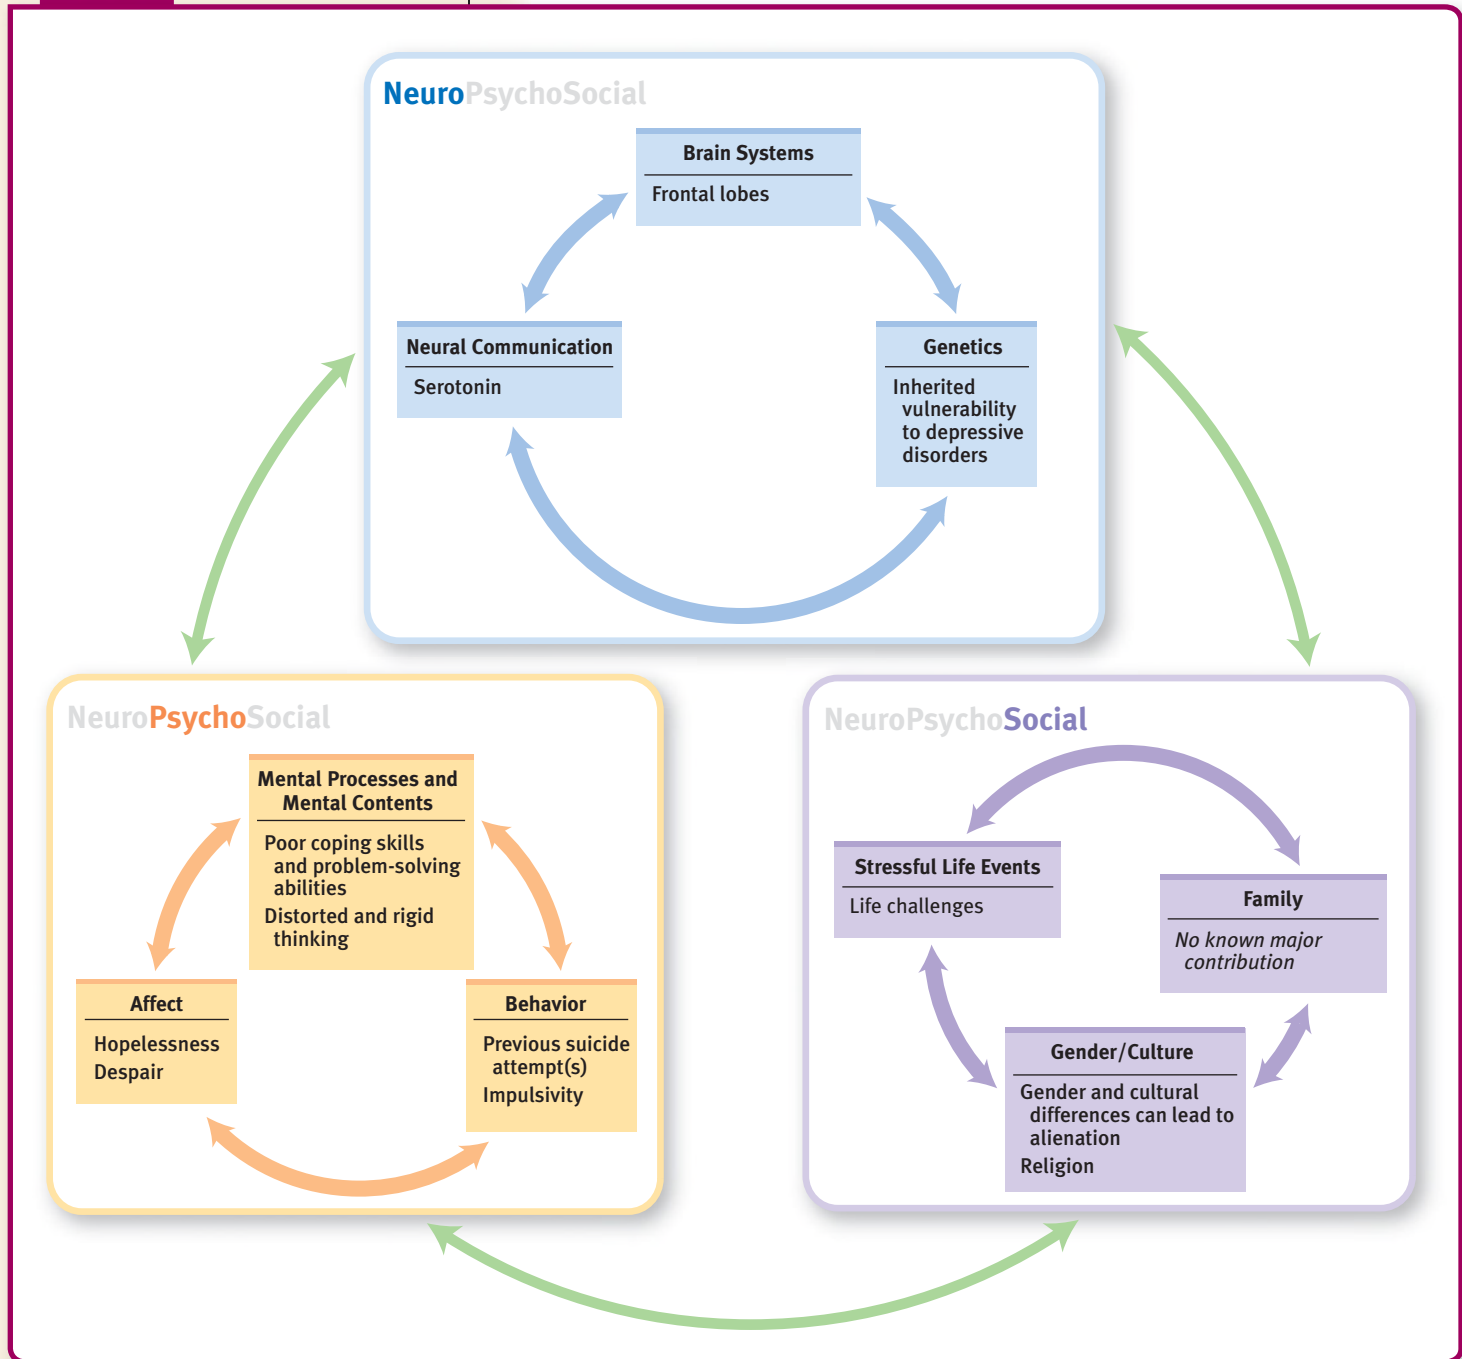

However, it is difficult to gauge the success of suicide prevention efforts. In the usual studies that evaluate treatments of DSM-IV-TR clinical disorders, potential participants can be identified through a clinical interview or questionnaire and assigned to a treatment group or a control group. However, there are many stumbling blocks in using similar research designs to evaluate suicide prevention methods. It's not clear, for instance, which participants should be included in a

Chris Hondros/Getty Images

In 2007, U.S. soldiers on active duty in Iraq and Afghanistan attempted or committed suicide at the highest level since records for military personnel began to be kept in 1980 (Priest, 2008). On average, five soldiers attempted suicide every day. Reasons for the high suicide rate include the strain on family relationships caused by long and repeated tours of duty, combat-related stress, and legal and financial problems. The Army's suicide prevention efforts include hiring additional mental health providers and instituting a program to teach junior Army leaders how to recognize signs of suicide intention in their troops and how to then intervene (Tyson, 2008).

Figure 6.8

6.8 ► Feedback Loops in Action: Suicide

study on suicide prevention: Those with any suicidal ideation, only those with a concrete plan, or those who have already tried once? Moreover, people who have already made at least one attempt may differ from those whose first attempt results in death. Another problem is determining what constitutes an appropriate control group. It would be unethical not to offer suicidal individuals in a control group the same level of services as those in the treatment group (De Leo, 2002b).

Despite such challenges in carrying out research, progress has been made in studying suicide prevention; let's review this progress.

Targeting Neurological Factors: Medication

Interventions that most commonly target neurological factors are medications (usually antidepressants) and, to a lesser extent, ECT for severe suicidal thoughts that do not respond to other treatments. However, it is unclear to what extent medications do prevent suicide. Khan and colleagues (2000) examined the U.S. Food and Drug Administration database that compared RCTs (randomized clinical trials) of newer antidepressants with placebos. The rates of both attempted and completed suicides were essentially the same for both groups. Nonetheless, before deciding that antidepressants have no effect on suicide, remember that people with serious suicidal intent are often excluded from RCTs that use placebo medications (see Chapter 4 for a discussion about exclusion criteria in RCTs). Thus, participants in the government database who attempted or completed suicide were probably not actively suicidal at the time they enrolled in the study.

Targeting Psychological Factors: Reducing Feelings of Hopelessness

For a person who is actively suicidal and who has contacted a mental health or medical professional, the first aim of suicide prevention is to make sure that the individual is safe. After this, crisis intervention helps the person to see past the hopelessness and rigidity that pervades his or her thinking, identifies whatever stressors have brought the individual to this point, helps him or her develop new solutions to the problems, and enhances the ability to cope.

In addition, a clinician tries to discover whether the person is depressed or abusing substances; if so, these problems, which may lead to suicidal thoughts or behaviors, should be treated (Reifman & Windle, 1995). Because most people who die by suicide had untreated depression, treatment for depression that targets psychological factors—typically CBT—can play a key role in suicide prevention.

Targeting Social Factors: Social Programs, Social Awareness

Ideally, prevention programs that decrease socially related risk factors and increase socially related protective factors should decrease the suicide rate. Thus, programs to prevent child abuse, to provide affordable access to mental health care (and so make it easier to obtain treatment for psychological disorders), to decrease substance abuse, and to increase employment may all help prevent suicides in the long term.

Part of the national suicide prevention plan in the United States is to increase awareness about suicide (Satcher, 1999), both among individuals who may feel suicidal and among the friends and family of someone feeling suicidal. The hope is that suicidal individuals will receive appropriate help before they commit suicide (see Table 6.15).

Table 6.15 ▶ Suicide Prevention: What to Do

What can you do if someone you know seems to be suicidal? According to the National Institute of Mental Health (Goldsmith et al., 2002), don't leave the person alone; get help by calling 911 or other trained emergency professionals. Also, try to make sure that potential means for committing suicide such as firearms or poisons are not easily accessible. Let the person know that you're concerned, and try not to be judgmental.

If you, or someone you know, are at risk for suicide, the following organizations can help:

- The National Hope Line Network
Phone: 800-SUICIDE. This will connect you with a crisis center in your area.
Website: <http://www.hopeline.com/>
- American Foundation for Suicide Prevention
Phone: 212-363-3500
Web site: <http://www.afsp.org>
- Suicide Prevention Advocacy Network
Phone: 770-998-8819
Web site: <http://www.spanusa.org>

FEEDBACK LOOPS IN PREVENTION: Suicide

To see how the three types of factors interact via feedback loops, let's examine a comprehensive suicide prevention program. From 1990 to 1995, the suicide rate among U.S. Air Force personnel aged 24–35 increased significantly. Recognizing

that those most likely to need help were often the least likely to seek it, the Air Force instituted a comprehensive program to prevent suicide. The program was designed to provide mental health services at the initial signs of distress or dysfunction and to change the norms about seeking help within the Air Force. The hope was that personnel could take advantage of such help without feeling stigmatized; the Air Force publicized that seeking help, either for oneself or for another, was a sign of responsibility and strength (Knox et al., 2003).

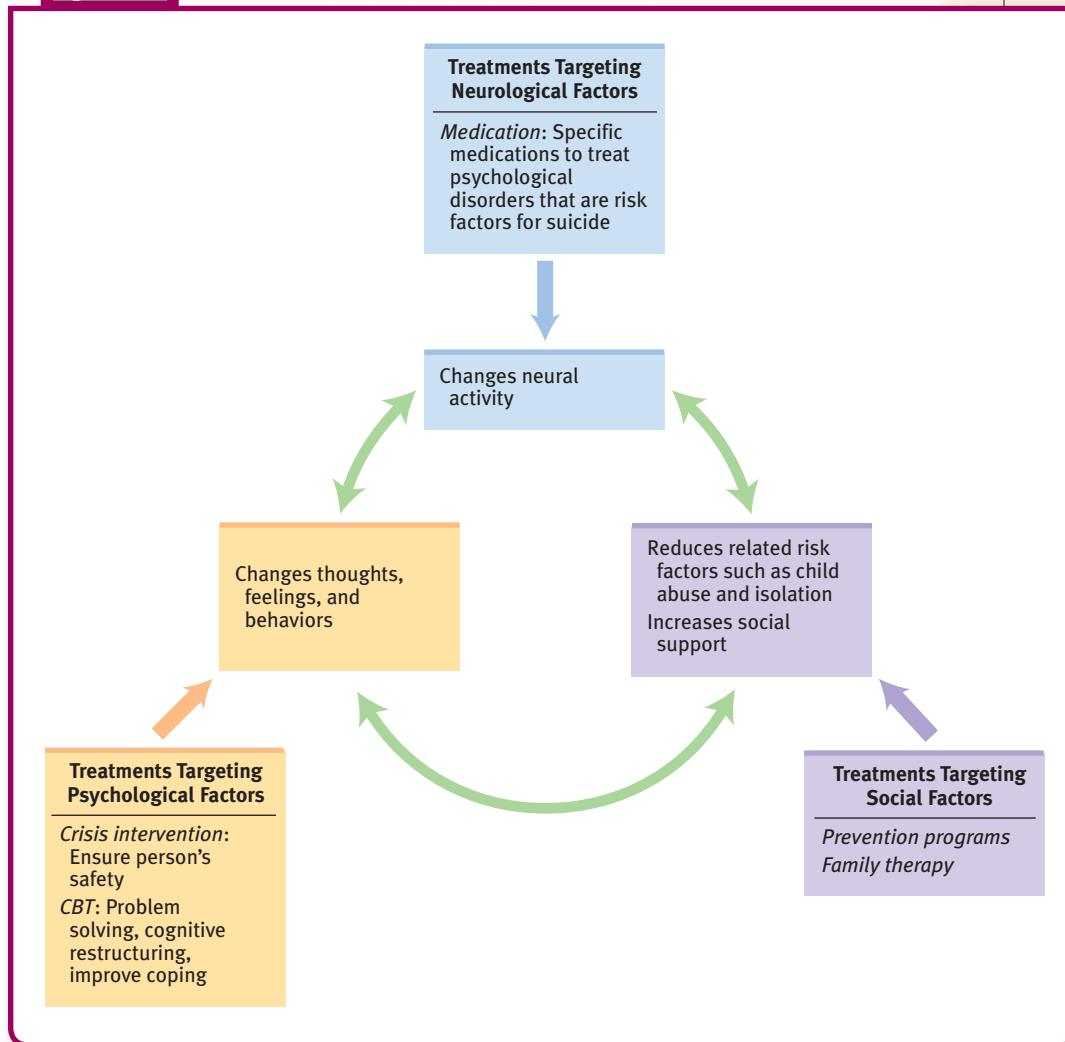

Taking advantage of this “experiment,” researchers compared the number of suicides among Air Force personnel in the 7 years before the program was fully instituted (1990–1996) with the number during the first 6 years after it was in full swing (1997–2002). As seen in Figure 6.9, the suicide rate fell by 33% after the program was fully instituted (McIntosh, 2003). (The emphasis on early intervention and decreased stigma had an added bonus: There was also a decrease in the homicide rate and in severe family violence among Air Force personnel from the first time period to the second. Thus, the prevention program yielded additional changes in social factors.) The Air Force has continued this suicide prevention program, and in the decade since the program was launched, the average annual suicide rate decreased by almost 30% compared to the decade before the program was launched (Pflanz, 2008). In the wake of increased suicide rates among soldiers who served in Iraq and Afghanistan, other branches of the military have stepped up their suicide prevention programs (Lorge, 2008). The Air Force program is being adapted by some college campuses in hopes of lowering the suicide rate among students (Koplewicz et al., 2007). Figure 6.10 illustrates the feedback loops involved in the prevention of suicide.

Figure 6.9

Source: Knox et al., 2003.

Figure 6.10**6.10 ► Feedback Loops in Preventing Suicide****Key Concepts and Facts About Suicide**

- Suicide is ranked 11th among causes of death in North America. Having thoughts of suicide or making a plan to carry it out may indicate a risk for suicide; behavioral changes (such as giving away possessions) may indicate a more serious risk. However, not everyone who attempts or commits suicide displays warning signs. In addition, certain self-harming behaviors may be parasuicidal behaviors rather than suicide attempts. The presence of certain psychological disorders, such as MDD, and a history of previous serious suicide attempts increase an individual's risk for suicide.
- Neurological factors that are associated with suicide include structural abnormalities in the frontal lobes and altered serotonin activity. In addition, suicide may be associated with a genetic risk for mood disorders. Psychological risk factors for suicide include poor coping and problem-solving skills, distorted and rigid thinking, and a sense of hopelessness. Variations in suicide rates across countries point to the role of social factors in influencing people to commit suicide.
- Suicide prevention efforts target neurological, psychological, and social factors. Neurological factors are targeted by medications. Treatments that target psychological factors are designed to ensure that the suicidal individual is safe and then to help the person see past the hopelessness and rigidity that pervade his or her thinking. Suicide prevention may also help the patient identify the stressors that led him or her to feel suicidal and develop new solutions to the problems. To address social factors, prevention programs may target risk factors that are associated with suicide, such as child abuse.

SUMMING UP

Summary of Depressive Disorders

A major depressive episode (MDE) is the building block for a diagnosis of major depressive disorder (MDD); when a person has an MDE, he or she is diagnosed with MDD. Symptoms of an MDE can arise in three areas: affect, behavior, and cognition.

Depression is becoming increasingly prevalent in younger cohorts. Depression and anxiety disorders have a high comorbidity—around 50%. MDD may arise with melancholic features, catatonic features, or psychotic features. Symptoms may also fall into less common patterns, as in atypical depression and chronic depression.

A diagnosis of dysthymic disorder requires fewer symptoms than does a diagnosis of MDD; however, the symptoms of dysthymic disorder must persist for a longer time than do symptoms of MDD. People who have both dysthymic disorder and MDD are said to have double depression.

Neurological factors related to depression include low activity in the frontal lobes, and abnormal functioning of dopamine, serotonin, and norepinephrine. The stress–diathesis model of depression highlights the role of increased activity of the HPA axis and of excess cortisol in the blood, but people with atypical depression have the opposite pattern—decreased activity in the HPA axis. Genes can play a role in depression.

Psychological factors that are associated with depression include a bias toward paying attention to negative stimuli, dysfunctional thoughts, rumination, a negative attributional style and learned helplessness.

Social factors that are associated with depression include stressful life events, social exclusion, and problems with social interactions or relationships. Culture and gender can influence the specific ways that symptoms of depression are expressed.

Neurological, psychological and social factors can affect each other through feedback loops, as outlined by the stress–diathesis model and Coyne's interactional theory of depression.

Biomedical treatments that target neurological factors for depressive disorders are medications and brain stimulation. Treatments for depression that target psychological factors include CBT. Treatments that target social factors include IPT and family systems therapy.

Thinking like a clinician

Suppose that a friend began to sleep through morning classes, seemed uninterested in going out and doing things together, and became quiet and withdrawn. What could you conclude or not conclude based on these observations? If you were concerned that these were symptoms of depression, what other symptoms would you look for? What if your friend's symptoms did not appear to meet the criteria for an MDE—what could you conclude or not conclude? If your friend was, in fact, suffering from depression, how might the three types of factors explain the depressive episode? What treatments might be appropriate?

Summary of Bipolar Disorders

The four building blocks for diagnosing bipolar disorders are major depressive episode (MDE), manic episode, mixed episode, and hypomanic episode. Symptoms of a manic episode include grandiosity, pressured speech, flight of ideas, distractibility, poor judgment, decreased need for sleep, and psychomotor agitation. A mixed episode is characterized by symptoms of both an MDE and a manic episode and may include psychotic features and suicidal thinking. A hypomanic episode involves mood that is persistently elated, irritable, or euphoric; unlike other mood episodes, hypomanic episodes do not impair functioning.

Researchers have characterized two types of bipolar disorder. Bipolar I disorder—usually more severe—requires only a manic or mixed episode; an MDE may occur but is not necessary for this diagnosis. Bipolar II disorder requires alternating hypomanic episodes and MDEs and no history of manic or mixed episodes. Both disorders may involve rapid cycling. Cyclothymic disorder is a more chronic but less intense version of bipolar II disorder.

Neurological factors that are associated with bipolar disorders include an enlarged and more active amygdala. Norepinephrine, serotonin, and glutamate are also involved. Bipolar disorders are influenced by genetic factors, which may influence mood disorders in general.

Psychological factors that are associated with bipolar disorders include the cognitive distortions and negative thinking associated with depression. Moreover, some people with bipolar I disorder may have residual cognitive deficits after a manic episode is over.

Social factors that are associated with bipolar disorders include disruptive life changes and social and environmental stressors. The different factors create feedback loops that can lead to a bipolar disorder or make the patient more likely to relapse.

Mood stabilizers are one treatment that targets neurological factors; when manic, patients may receive an antipsychotic medication or a benzodiazepine.

Treatment that targets psychological factors—particularly CBT—helps patients recognize warning signs of mood episodes, develop better sleeping strategies, and, when appropriate, stay on medication.

Treatments that target social factors include interpersonal and social rhythm therapy (IPSRT), which can increase the regularity of daily events and decrease social stressors; family therapy and education; and group therapy or a self-help group, which is intended to decrease shame and isolation.

Thinking like a clinician

You get in touch with a friend from high school who tells you that she recently had a hypomanic episode. What are two possible DSM-IV-TR diagnoses that she might have had (be specific)? What will determine which diagnosis is most appropriate? What are a few of the symptoms that are hallmarks of a hypomanic episode? What would be the difference in symptoms if your friend instead experienced a manic episode? Would her diagnosis change or stay the same? Explain. How do the three types of factors (neurological, psychological, and social) explain why bipolar disorders develop? What would be the most appropriate ways to treat bipolar disorders?

Summary of Suicide

Having thoughts of suicide or making a plan to carry it out may indicate a risk for suicide; behavioral changes (such as giving away possessions) may indicate a more serious risk. However, not everyone who attempts or commits suicide displays warning signs. In addition, certain self-harming behaviors may be parasuicidal behaviors rather than suicide attempts. The presence of certain psychological disorders, such as MDD, and a history of previous serious suicide attempts increase an individual's risk for suicide.

Neurological factors that are associated with suicide include structural abnormalities in the frontal lobes and altered serotonin activity. In addition, suicide may be associated with

a genetic risk for mood disorders. Psychological risk factors for suicide include poor coping and problem-solving skills, distorted and rigid thinking, and a sense of hopelessness. Variations in suicide rates across countries point to the role of social factors in influencing people who commit suicide.

Suicide prevention efforts target neurological, psychological, and social factors. Neurological factors are targeted by medications. Treatments that target psychological factors are designed to ensure that the suicidal individual is safe and then to help the person see past the hopelessness and rigidity that pervade his or her thinking and develop new solutions to problems. To address social factors, prevention programs may target risk factors that are associated with suicide, such as child abuse and substance abuse.

Thinking like a clinician

Based on what you have learned about suicide, explain Kay Jamison's suicide attempt in terms of the three types of factors. Identify how the neurological, psychological and social factors might have influenced each other

via feedback loops. From what you know of her, what were Jamison's risk and protective factors?

Key Terms

Mood disorders (p. 191)

Anxiety Disorders

Howard Hughes is famous for many things: He was an industrialist, creating Hughes Aircraft Company and designing the planes his company built; he was an aviator who broke flying records; he was the owner of hotels and casinos; he was a reclusive billionaire who directed an Academy Award-winning film. Born in 1905 to wealthy parents in Houston, Texas, Hughes set his sights on accomplishing feats that people said couldn't be done, and he achieved them nonetheless. During his lifetime, people around the world recognized his name and his accomplishments.

Earl Campbell, born in 1955, gained considerable fame as a National Football League (NFL) running back from 1978 to 1985. Campbell was such an outstanding athlete that he was voted most valuable player for each of his first 3 years with the NFL. He was later inducted into the Football Hall of Fame and went on to achieve in other areas of life: He became a food manufacturer, restaurateur, and businessman.

Unlike Hughes, Campbell was not born to wealth and privilege. He grew up in a small Texas town with 10 brothers and sisters, all living in a three-bedroom house that had its bathroom outdoors. Between May and August, the whole family worked in the nearby rose fields, cutting the flowers; in the autumn, they hauled hay for local farmers. When Campbell was 11 years old, his father died of a heart attack; his mother held the family together with her strong sense of morality and work ethic, which she instilled in her children.

Both of these men—Hughes and Campbell—possessed remarkable talents and abilities and an unusually strong drive to achieve. But they also shared another characteristic—they both suffered from symptoms of anxiety disorders. *Anxiety disorders* involve significant fear, agitation, and nervousness and can impair functioning in any or all spheres of life, including school, work, and interpersonal relationships. Both Hughes and Campbell developed such severe anxiety symptoms that they were unable to work effectively. However, the specific forms taken by their anxiety symptoms differed, as we'll see.

In this chapter, we discuss six types of anxiety disorders that are described in DSM-IV-TR: generalized anxiety disorder, panic disorder, social phobia, specific phobias, obsessive compulsive disorder, and posttraumatic stress disorder. We'll start with a general discussion of what anxiety is and identify some of the common features of the

Howard Hughes and Anxiety Disorders

AP Photo

In his 30s, former NFL player Earl Campbell suddenly developed symptoms of anxiety—racing heart and trouble breathing—which frightened him, as they would most people.

Anxiety

A sense of agitation or nervousness, which is often focused on an upcoming possible danger.

different anxiety disorders. In the process we'll first examine Earl Campbell—his life, the nature of his anxiety symptoms, the disorders most relevant to his symptoms, and how he responded to and handled his anxieties. Once we have examined the disorders most applicable to Campbell's symptoms, we then turn to Howard Hughes—the nature of his constellation of anxiety symptoms, the disorders most relevant to these symptoms, and how he responded to and handled his anxieties.

Common Features of Anxiety Disorders

Earl Campbell played high school football and, after graduating, became a star running back on the University of Texas–Austin football team. From there, he went on to play for the Houston Oilers in the NFL. At age 24, he married Reuna, a woman from his hometown whom he had been dating for 10 years. Five years later, they had their first child, and 2 years after that, at the age of 31, Campbell retired from football.

Campbell went on to work for the University of Texas–Austin as a goodwill ambassador, representing the school at various functions, and helping student-athletes commit to their studies. One day, when Campbell was driving from Austin to Dallas, he stopped at a traffic light and had an unusual experience:

Out of the blue, my heart started racing. I felt my chest. Then I broke into a cold sweat, began hyperventilating, and became convinced I was having a heart attack. The people in the car next to mine seemed totally unaware that anything was wrong. My heart just kept racing. I couldn't stop it. I was going to die. How could I stop it? It was getting worse. I was dying! The driver behind me started blowing his horn. The light had turned green. I needed help. I couldn't get out of the car. "God help me!" I prayed. Then it stopped—just like that, my heart stopped racing. I put my hand to my heart again. It felt normal. My hands and arms were covered with a cold clammy sweat. I wiped the perspiration from my face and look[ed] at myself in the rearview mirror. For the first time in my life, I caught sight of a frightened Earl Campbell and I didn't like it . . .

(Campbell & Ruane, 1999, pp. 83–84)

Not only did Campbell have frightening bodily sensations, he also developed worries about "the little details that most people don't even think about. They weigh on me and tie up my mind. I am continually inundated with intrusive thoughts related to everything I say or do. Do I look okay? Am I walking right? Did I do this right? That right? Why is everyone looking at me? Is it because I'm Earl Campbell, or is it because there's something wrong with me?" (Campbell & Ruane, 1999, p. 199).

Campbell's experiences involve anxiety. In this section, we consider in detail what anxiety is and its relation to the fight-or-flight response. We then examine the common cooccurrence of anxiety disorders and depression.

What Is Anxiety?

Like the term *depression*, the words *anxiety* and *anxious* are used in everyday speech. But what do mental health professionals and researchers mean when using these terms? **Anxiety** refers to a sense of agitation or nervousness, which is often focused on an upcoming potential danger.

We all feel afraid and anxious from time to time. These feelings can be adaptive, signaling the presence of a dangerous stimulus and leading us to be more alert, which heightens our senses. For instance, if you are walking alone down a dark, quiet street late at night, you might be able to hear particularly well or be more sensitive to another person's presence behind you. Such heightened senses can be adaptive on a dark street. Should you hear or sense someone, you may choose to head quickly for a well-lit and busier street. Similarly, a moderate level of anxiety before a test or presentation can enhance your performance (Deshpande & Kawane, 1982)—and, in fact, the absence of anxiety can lead to a lackluster

performance, even if you know the material well. Thus, feeling afraid or anxious can be normal and adaptive. Extreme anxiety, however, is a persistent, vague sense of dread or foreboding when not in the presence of a feared stimulus (such as a snake or a plane trip). Such extreme anxiety can arise in response to a high level of fear of a particular stimulus and is sometimes called **anxious apprehension** (Barlow, 2002a). An **anxiety disorder** involves extreme anxiety, intense arousal, and extreme attempts to avoid stimuli that lead to fear and anxiety. These emotions, or the efforts to avoid experiencing them, can create a high level of distress, which can interfere with normal functioning.

The Fight-or-Flight Response Gone Awry

Campbell describes some of the frightening physical sensations he experienced in this way: “Visualize yourself just sitting back in a chair, relaxing. Suddenly, your heart starts racing as if you had just run a hundred-yard dash. You break into a cold sweat. You have trouble breathing. You feel there is nothing you can do to stop all of these things from happening” (Campbell & Ruane, 1999, p. i). Campbell was describing the effects of the **fight-or-flight response** (also called the *stress response*; see Chapter 2), which occurs when an individual perceives a threat. Suppose you think you see a mugger lurking on a dark doorstep as you are hurrying home, alone, late at night. Your brain and body respond as if you must either fight or take flight. The stress response prepares your body to exert physical energy for an action, either fighting the threat or running away from it. It does not matter whether there is an actual threat. Your body automatically responds because you *perceive* a threat. Your body responds in a number of ways (for a more complete list, see Figure 7.1), most notably by:

- increasing your heart rate and breathing rate (in order to provide more oxygen to your muscles and brain),
- increasing the sweat on your palms (a small amount, which helps you grip better — yet not so much as to make your palms become slippery), and
- dilating your pupils (in order to let in more light and help you to see better).

Your body responds this way even to threats that do not require a lot of physical energy, such as—for many people—speaking in front of a group of people (or even *thinking* about speaking in front of them) or taking a pop quiz. In such cases, your body gets prepared, but most of the physical preparations aren’t really necessary.

This fight-or-flight response underlies the fear and anxiety involved in almost all anxiety disorders. Some people have an overactive stress response—they have higher levels of arousal during the stress response. Other people may not have an overactive stress response, but they may misinterpret their arousal during the fight-or-flight response and attribute the bodily sensations to a physical ailment. They might, for instance, interpret an increased heart rate as a heart attack. In either case, people come to feel afraid or anxious about the physical sensations of the stress response or the conditions that seem to have caused the response. When their arousal feels as if it is getting out of control, they may start to feel **panic**, which is an extreme sense (or fear) of imminent doom, together with an extreme stress response (Bouton, Mineka, & Barlow, 2001)—what Campbell experienced sitting in his car at a stoplight. Some people who become panicked develop a **phobia** (a term derived from the Greek word for fear, *phobos*), which is an exaggerated fear of an object or a situation, together with an extreme avoidance of the object or situation. Such avoidance can interfere with everyday life. For instance, at one point, Campbell avoided crowded rooms because he thought they might bring on the uncomfortable physical sensations he’d experienced.

Unfortunately, significant anxiety and phobias are not unusual or rare. In the United States, anxiety disorders are the most common kind of mental disorder (Barlow, 2002a); around 15% of people will have some type of anxiety disorder in their

Anxious apprehension

Anxiety that arises in response to a high level of fear of a particular stimulus.

Anxiety disorder

A category of psychological disorders in which the primary symptoms involve extreme anxiety, intense arousal, and/or extreme attempts to avoid stimuli that lead to fear and anxiety.

Fight-or-flight response

The automatic neurological and bodily response to a perceived threat; also called the *stress response*.

Panic

An extreme sense (or fear) of imminent doom, together with an extreme stress response.

Phobia

An exaggerated fear of an object or a situation, together with an extreme avoidance of the object or situation.

Figure 7.1

7.1 ► The Fight-or-Flight Response The fight-or-flight response activates the sympathetic nervous system and prepares the body for a significant expenditure of physical energy. Specifically, the sympathetic nervous system gives rise to deeper and quicker breathing to deliver more oxygen to the blood, increased blood flow to muscles and brain (to give them more oxygen), decreased blood flow to skin (which is why people blanch when afraid), more glucose released from the liver into the blood (to provide energy for muscles, organs, and brain), increased sweat on the palms (a small amount, which improves the grip), pupil dilation for better visual acuity, slowed digestion in the stomach and intestines (and an urge to empty the system through urination, defecation, or vomiting). The parasympathetic nervous system typically brings these effects back to the normal state.

lifetimes (Somers et al., 2006). The prevalence rates of anxiety disorders diagnosed by family doctors almost doubled from 1990 to 2003, but it is not clear whether this trend represents a true increase in the number of cases, better recognition of anxiety disorders by the physicians, or both (Skaer, Sclar, & Robison, 2008). Women are twice as likely as men to be diagnosed with one of the anxiety disorders (Somers et al., 2006), although the reasons for this difference are not well understood. Some

explanations point to biological differences, such as the hormonal shifts that occur during a woman's childbearing years (Ginsberg 2004); the gender difference in anxiety disorders coincides with the onset of puberty (as is the case with depression; see Chapter 6). Other explanations for the gender difference point to cultural factors (Pigott, 1999): Men tend to be reluctant to acknowledge symptoms of anxiety because they fear that admitting such feelings might undercut the masculine image they project to others.

Comorbidity of Anxiety Disorders

As you'll see throughout this text, symptoms of anxiety or avoidance may occur in many psychological disorders, including *mood disorders* (Chapter 6), *somatization disorder* (Chapter 8), *body dysmorphic disorder* (Chapter 8), and *anorexia nervosa* (Chapter 11). Clinicians must determine whether the anxiety and avoidance symptoms are the *primary* cause of the disturbance or a by-product of another type of problem. In the case of anorexia nervosa, for example, when someone gets anxious about eating high-calorie foods, the anxiety is *secondary* to larger concerns about food, weight, and appearance.

Anxiety and depression often occur together; about 50% of people with an anxiety disorder are also depressed (Brown et al., 2001). For Earl Campbell, depression followed anxiety. A couple of weeks after his first anxiety episode, on the first morning in his new house in Austin, Campbell experienced debilitating depression settling on him:

The moment I woke up in the morning, a heaviness enveloped me. I couldn't avoid it. I would open my eyes and start crying. I would sit in the bedroom all day long, wearing pajamas and sunglasses, the curtains closed against the daylight. Life had slipped into slow motion. Sometimes I'd sit in a daze on the couch, watching Reuna unpacking boxes and organizing the house. I would just sit there in pain. I began to have terrible headaches. The depression would not let up. I told Reuna I was sure I was going to die. She knew I was quite serious.

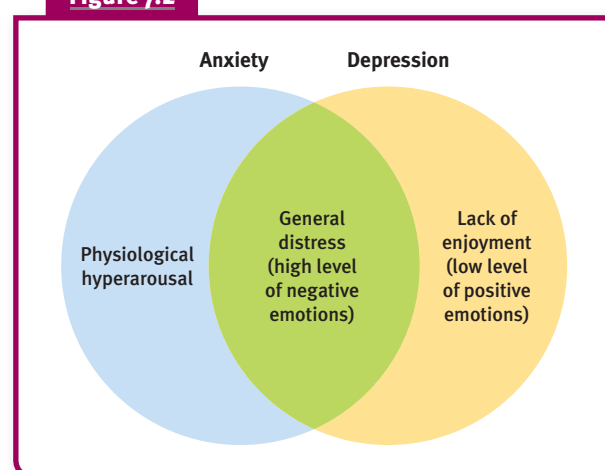

(Campbell & Ruane, 1999, p. 92)

Researchers and clinicians are trying to discover why there is such high comorbidity between anxiety disorders and depression. Some researchers have proposed a three-part model of anxiety and depression that specifies the ways in which the two kinds of disorders overlap and the ways in which they are distinct (Clark & Watson, 1991; Mineka, Watson, & Clark, 1998). This model has been supported by subsequent research (Joiner, 1996; Olino et al., 2008). The three parts of the model are as follows (see Figure 7.2):

1. *High level of negative emotions*, which include general distress. Both anxiety and depressive disorders can involve poor concentration, sleep disturbances, and irritability, as well as anxious apprehension. This part of the model represents the common factor shared by anxiety disorders and depression (and other disorders as well).
2. *Low level of positive emotions*. Symptoms of depression include a lack of enjoyment and slowed motor functioning. Low positive affect is a symptom of depression, but generally not a symptom of anxiety disorders.
3. *Physiological hyperarousal* (overarousal), which is found in anxiety disorders, but not in depression.

Approximately 10–25% of those with anxiety disorders also abuse or are dependent on alcohol (Bibb & Chambless, 1986; Otto et al., 1992). Among people with phobias, the alcohol use usually occurs *after* the anxiety symptoms develop. Among those with other kinds of anxiety disorders, alcohol use may either precede or follow the onset of the anxiety disorder (Swendsen et al., 1998).

Figure 7.2

7.2 ▶ Tripartite Model of Anxiety and Depression

Anxiety and depression have in common a high level of negative emotions, but each has unique elements: Anxiety generally involves a very high level of physiological arousal, whereas depression involves a low level of positive emotions.

People with phobias, such as musicians with performance anxiety (stage fright), may use alcohol to relieve their anxiety symptoms. However, using alcohol in this way can lead to abuse or dependence.

Key Concepts and Facts About Common Features of Anxiety Disorders

- The key symptoms of anxiety disorders are extreme anxiety, intense arousal, and attempts to avoid stimuli that lead to fear and anxiety.
- The fight-or-flight response arises when people perceive a threat; when the arousal feels out of control—either because the individual has an overactive stress response or because he or she misinterprets the arousal—the person may experience panic. In response to the panic, some people develop a phobia of stimuli related to their panic and anxiety symptoms.
- Anxiety disorders frequently co-occur with other psychological disorders, such as depression or substance-related disorders. Mental health clinicians must determine whether the anxiety symptoms are the primary cause of the problem or are the by-product of another type of disorder.
- The high comorbidity of depression and anxiety disorders suggests that the two disorders share some of the same features, specifically high levels of negative emotions and distress—which can lead to concentration and sleep problems and irritability.

Generalized Anxiety Disorder

Earl Campbell became a worrier—even during the best of times:

On a day when life seems absolutely wonderful—say, a beautiful fall Saturday or Sunday when I'm watching one of my boys play football—I'll often be overcome by the fear that it will all come to an end somehow. It's just too good. Something bad is going to ruin it for me. This past year was the most difficult one I've had . . . Tyler [his son] was in the fifth grade, and I worried the entire year. I was in the fifth grade when my father died, and I thought my fate was sealed. I was scared I would die and my boys would have to go through life without a father, the way I did.

(Campbell & Ruane, 1999, p. 204)

Worrying is a normal part of life, but some people worry more than others. How much is “too much” worrying?

What Is Generalized Anxiety Disorder?

Generalized anxiety disorder (GAD) is characterized by uncontrollable worry and anxiety about a number of events or activities (which are not solely the focus of another Axis I disorder, such as about having a panic attack) (see Table 7.1; American Psychiatric Association, 2000). The worry and anxiety among individuals suffering from GAD primarily focus on family, finances, work, and illness (Sanderson & Barlow, 1990); Earl Campbell worried mostly about family and illness; other people may worry about minor matters (Craske, Rapee, Jackel, & Barlow, 1989). In contrast to most people, people with GAD worry even when things are going well. Moreover, their worries intrude into their awareness when they are trying to focus on other thoughts—and they cannot stop worrying (American Psychiatric Association, 2000). Symptoms are present for at least half the days during a 6-month period. Like A. H., discussed in Case 7.1, people with GAD feel a chronic, low level of anxiety or worry about many things. Moreover, the fact that they constantly worry in itself causes them distress.

CASE 7.1 ► FROM THE OUTSIDE: Generalized Anxiety Disorder

A. H. was a 39-year-old divorced mother of two (son aged 12, daughter aged 7) who worked as a bank manager. However, she had become concerned about her ability to concentrate on and remember information while at work. A. H. had made some “financially disastrous” mistakes, and was now—at the suggestion of her supervisor—taking some vacation time to “get her head together.” Because of her concentration and memory problems, it had been taking her longer to complete her work, so she had been arriving at work 30 minutes early each day, and often took work home. She reported being unable to relax, even outside of work, and at work it was hard to make decisions because she ruminated endlessly (“Is this the right decision, or should I do that?”), and hence tried to avoid making decisions altogether. Her concentration and memory problems were worst when she was worried about some aspect of life, which was most of the time. She reported that 75% of her waking life each day was spent in a state of anxiety and worry. In addition to worrying about

Generalized anxiety disorder (GAD)

The anxiety disorder characterized by uncontrollable worry and anxiety about a number of events or activities that are not solely the focus of another Axis I disorder.

her performance at work, she worried about her children's well being (whether they had been hurt or killed while out playing in the neighborhood). She also worried about her relationships with men, and minor things such as getting to work on time, keeping her house clean, and maintaining regular contact with friends and family. A. H. recognized that her fears were both excessive and uncontrollable, but she couldn't dismiss any worry that came to mind. She was irritable, had insomnia, frequent muscle tension and headaches, and felt generally on edge.

(Adapted from Brown & Barlow, 1997, pp. 1–3)

Table 7.1 ▶ DSM-IV-TR Diagnostic Criteria for Generalized Anxiety Disorder (GAD)

- A.** Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).
- B.** The person finds it difficult to control the worry.
- C.** The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms present for more days than not for the past 6 months).
Note: Only one item is required in children.
 - (1) restlessness or feeling keyed up or on edge
 - (2) being easily fatigued
 - (3) difficulty concentrating or mind going blank
 - (4) irritability
 - (5) muscle tension
 - (6) sleep disturbance (difficulty falling or staying asleep, or restless unsatisfying sleep)
- D.** The focus of the anxiety and worry is not confined to features of an Axis I disorder, e.g., the anxiety or worry is not about having a Panic Attack (as in Panic Disorder [discussed later in this chapter]), being embarrassed in public (as in Social Phobia [discussed later in this chapter]), being contaminated (as in Obsessive-Compulsive Disorder [discussed later in this chapter]), being away from home or close relatives (as in Separation Anxiety Disorder [Chapter 14]), gaining weight (as in Anorexia Nervosa [Chapter 10]), having multiple physical complaints (as in Somatization Disorder [Chapter 8]), or having a serious illness (as in Hypochondriasis [Chapter 8]), and the anxiety and worry do not occur exclusively during Posttraumatic Stress Disorder [discussed later in this chapter].
- E.** The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- F.** The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism) and does not occur exclusively during a Mood Disorder [Chapter 6], a Psychotic Disorder [Chapter 12], or a Pervasive Developmental Disorder [Chapter 14].

Source: Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Text Revision, Fourth Edition, (Copyright 2000) American Psychiatric Association.

Because the symptoms are chronic (lasting at least 6 months) and because many people with GAD can usually function adequately in some areas of their daily lives, they come to see their worrying and anxiety as a part of themselves, not as a disorder. However, as happened to A. H., not having control over anxious thoughts and worrying can lead to problems in work and social life. The worrying may be so intrusive that people feel restless, have difficulty concentrating or sleeping, and become irritable. See Table 7.2 for more facts about GAD.

As noted in Table 7.2, GAD and depression have an extremely high comorbidity. Among people who have both disorders at the same time, only 27% eventually experience remission, compared to 48% of those who have only GAD and 41% of those who have only depression (Schoevers et al., 2005). People with both disorders are also likely to have

The content of the worries of people with GAD is influenced by their culture and the types of catastrophic events most likely to occur in their locale. Those who live along the Gulf coast of the United States may worry about hurricanes; those who reside in California may worry about earthquakes.

AP Photo/Dave Martin

Table 7.2 ▶ Generalized Anxiety Disorder Facts at a Glance**Prevalence**

- Approximately 5% of people will develop GAD in their lifetime, with women over age 40 at highest risk (approximately 10% of this group will develop the disorder) (American Psychiatric Association, 2000; Kessler et al., 2005; Somers et al., 2006).
- Primary care physicians report that their patients suffer from GAD more frequently than other anxiety disorders (Lieb, Becker, & Altamura, 2005; Wittchen & Hoyer, 2001).

Comorbidity

- GAD occurs very frequently with depression, with up to 80% of those having GAD during their lives also experiencing depression at some point (Judd et al., 1998).
- Approximately half of the people who have both GAD and depression during their lifetimes have both disorders at the same time (Ansseau et al., 2005).

Onset

- Approximately half the people with GAD develop the disorder between the ages of 10 and 19, whereas most others, particularly women, develop it sometime after turning 40 (Hoehn-Saric, Hazlett, & McLeod, 1993; Wittchen & Hoyer, 2001).

Course

- Once someone has GAD, its course is likely to be chronic, with symptoms fluctuating in response to stress.

Gender Differences

- Twice as many women as men are diagnosed with GAD.

Cultural Differences

- The content of the worries of people with GAD is shaped by their culture, their personal experiences, and the environment in which they live. Some people worry about catastrophic events, such as natural disasters; others worry about human-caused calamities, such as nuclear war or terrorist acts.

Source: Unless otherwise noted, the source for information is American Psychiatric Association, 2000.

had their symptoms arise at a younger age (Moffitt et al., 2007), to have more severe symptoms of each disorder, and to function less well than those who have only one of the two disorders (Zimmerman & Chelminski, 2003). Among people over 50 years old—the age group in which GAD is most common—depression often arises after GAD (Lenze et al., 2005; Schoevers et al., 2005). The high comorbidity also suggests that GAD and depression may reflect different facets of the same underlying problem, which is rooted in distress, worry, and rumination (Schoevers et al., 2003).

Understanding Generalized Anxiety Disorder

GAD can be best understood by using the neuropsychosocial approach to examine its etiology—by considering neurological, psychological, and social factors and the feedback loops among them. Each type of factor, by itself, seems to be necessary but not sufficient to give rise to this disorder. Neurological and psychological factors set the stage, and social factors can trigger the symptoms.

Neurological Factors

Let's examine the role of neurological factors in GAD. We'll see that the right hemisphere of the brain appears to play a special role in GAD, that a complex mix of neurotransmitters is involved in the disorder (largely by affecting the autonomic nervous system and brain areas involved in registering reward), and that genetics sets the stage by predisposing someone to develop GAD.

Brain Systems

The brain ultimately controls the body's responses, and thus GAD must involve the brain in some way. However, researchers are only beginning to identify the precise ways in which large-scale brain mechanisms are altered to produce GAD (Nutt, 2001). For example, they have found that patients with GAD have more gray and white matter in the superior temporal gyrus, an area used in hearing and language comprehension, than do individuals who do not have this disorder. Moreover, this brain area is strikingly larger in the right hemisphere than the left in patients with GAD, and the size difference is more extreme for people who have more severe anxiety (De Bellis et al., 2002). It is possible that this additional cortex leads people with GAD to form certain associations (such as of being in danger when in common situations or suffering dangerous consequences after performing common actions) more easily than do other people, but at present this is only a hypothesis.

The role of the right hemisphere was also evident in an fMRI study in which adolescent patients with GAD and adolescents in a control group viewed angry and neutral faces (Monk et al., 2006). The researchers found that a key part of the right frontal lobe was more strongly activated for the patients than for the controls when the participants saw angry faces. However, patients who showed greater activation in this area had less severe anxiety. These results are only suggestive, but might indicate that this area is involved in a coping activity, such as attempting to regulate bodily responses; in fact, the frontal lobes have many connections to the limbic system, including connections to the amygdala, which plays a key role in fear (e.g., LeDoux, 1996, 2000), and to the autonomic nervous system (Gabbott et al., 2005; Ghashghaei & Barbas, 2002; Teves et al., 2004).

The connections from the frontal lobes to the autonomic nervous system may play a particular role in GAD—but, unlike most types of anxiety disorders, GAD isn't associated with cranked up sympathetic nervous system activity (Marten et al., 1993). Instead, GAD is associated with decreased arousal that arises from an unusually responsive parasympathetic nervous system. The parasympathetic nervous system tends to cause effects opposite to those caused by the sympathetic nervous system. So, for instance, heightened parasympathetic activity slows heart rate, stimulates digestion and the bladder, and causes pupils to contract (Barlow, 2002a). When an individual with GAD perceives a threatening stimulus, his or her subsequent worry temporarily *reduces* any arousal (Borkovec & Hu, 1990), suppresses negative emotions (see Figure 7.2), and produces muscle tension (Barlow, 2002a; Pluess, Conrad, & Wilhelm, 2009). These facts are in stark contrast to Earl Campbell's symptoms, which suggest that he did not have GAD.

Neural Communication

Although the frontal lobes of patients with GAD are normal in size, the dopamine in the frontal lobes of these patients does not function normally (Stein, Westenberg, & Liebowitz, 2002). In fact, numerous studies suggest that a wide range of neurotransmitters, including gamma-aminobutyric acid (GABA), serotonin, and norepinephrine, may not function properly in people with GAD (Nutt, 2001). These neurotransmitters affect, among other things, people's response to reward, their motivation, and how effectively they can pay attention to stimuli and events.

Genetics

Studies of the genetics of GAD have produced solid evidence that GAD has a genetic component. The heritability estimate for GAD is at least 15–20% (Hettema, Prescott, & Kendler, 2001) and possibly almost 40% (Scherrer et al., 2000) and the disorder is equally heritable for men and women (Hettema, Prescott, & Kendler, 2001). However, much of this disorder may rest on a tendency to become anxious, which can be manifested in a number of different ways. For example, much of the genetic basis of GAD is shared with panic disorder (Chantarujikapong et al., 2001; Scherrer et al., 2000) and with posttraumatic stress disorder (Chantarujikapong et al., 2001). Moreover, if one family member has GAD, other family members are

A construction forewoman talks with a member of her crew. People who have GAD may be hypervigilant for possible threats in their environment, for example, constantly scanning the boss's face for possible signs of displeasure.

Hypervigilance

A heightened search for threats.

likely to have GAD or depression, which suggests a common underlying genetic vulnerability (Gorwood, 2004; Kendler et al., 2007).

Psychological Factors: Hypervigilance and the Illusion of Control

Psychological factors that contribute to GAD generally involve three characteristic modes of thinking and behaving: being particularly alert for possible threats, feeling that the worrying is out of control, and sensing that the worrying prevents panic.

1. People with GAD pay a lot of attention to stimuli in their environment, searching for possible threats. This heightened search for threats is called **hypervigilance**.
2. People with GAD typically feel that their worries are out of control and that they can't stop or alter the pattern of their thoughts, no matter what they do.
3. The mere act of worrying prevents anxiety from becoming panic (Craske, 1999), and thus the act of worrying is negatively reinforcing (Borkovec, 1994a; Borkovec et al., 1999). The worrying does not help the individual cope with the problem at hand, but it does give him or her the *illusion* of coping, which temporarily decreases anxiety about the perceived threat. Some people think that if they worry, they are actively addressing a problem. But they are not—worrying is not the same thing as effective problem solving; the original concern isn't reduced by the worrying and it remains a problem, along with the additional problem of chronic worrying.

Social Factors: Stressors

Stressful life events, such as a death in the family, friction in a close relationship, or trouble on the job, can trigger symptoms of GAD in someone who is neurologically and psychologically vulnerable to developing it. For people who develop GAD after age 40, the disorder often arises after a significant stressor occurs.

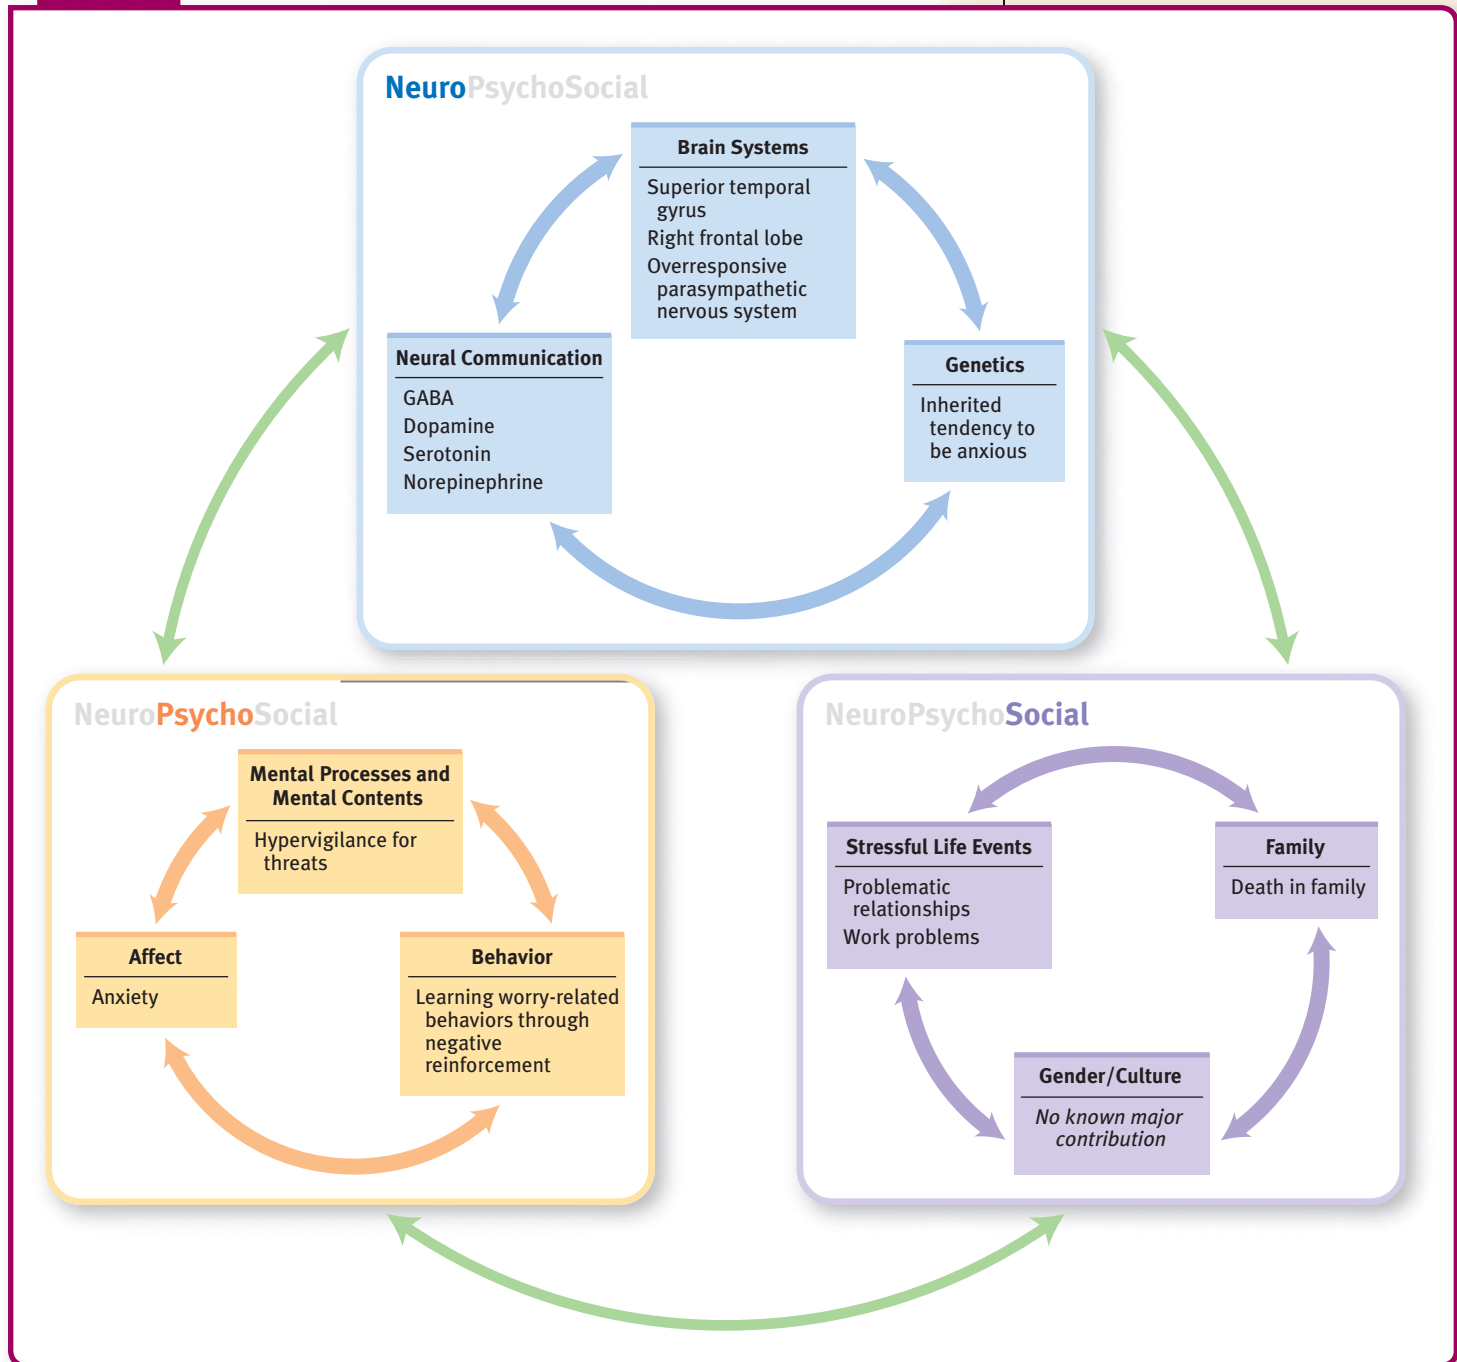

GAD also appears to be related more directly to relationships. In one interesting study, researchers found that college students with GAD rated themselves as having more severe global relationship problems (often being too compliant and deferential to others) than did college students in a control group. However, when friends of the students with GAD and friends of the control participants were asked to rate the severity of relationship problems of the participants in the study, the ratings did not differ for the GAD and control participants (Eng & Heimberg, 2006). This means that the GAD students felt that they had problems with relationships, but people close to them didn't see it that way. People with GAD may experience increased stress if they view themselves as having serious problems in relationships. Increased stress, in turn, can lead to distress and negative emotions that can be difficult to manage and regulate (Mennin, Turk et al., 2004).

FEEDBACK LOOPS IN ACTION:

Understanding Generalized Anxiety Disorder

Stressful life experiences (typically social factors) can trigger the onset of GAD, but most people who experience stressful periods in their lives—even extreme stress—never develop this disorder. Moreover, people who do develop GAD often report that they were afraid and avoidant as children (American Psychiatric Association, 2000), which may be explained by abnormal neurological or physiological (perhaps hormonal) functioning. However, such abnormal functioning in childhood could arise from genes, might develop in childhood because of early life experiences, or could be caused by some combination of the two. To develop GAD, a person probably must experience three factors (see Figure 7.3): abnormal neurological functioning (which may reflect abnormal levels of GABA or another neurotransmitter), learning certain kinds of worry-related behaviors such as hypervigilance for threats, and undergoing a highly stressful event or set of events such as a death in the family. Any one of these alone—and probably any two of these—will not cause GAD.

Figure 7.3

7.3 ► Feedback Loops in Action: Generalized Anxiety Disorder

Treating Generalized Anxiety Disorder

Treatment for GAD can target neurological, psychological, or social factors, although neurological or psychological factors are the predominant focus of treatments. As usual, interventions targeting any type of factor have ripple effects to the other factors.

Targeting Neurological Factors: Medication

The antianxiety medication *buspirone* (Buspar) effectively reduces the symptoms of GAD, probably by decreasing serotonin release. Serotonin facilitates changes in

the amygdala that underlie learning to fear objects or situations (Huang & Kandel, 2007); thus, reducing serotonin may make learning to fear or worry about specific objects or situations more difficult. Moreover, other studies have shown that decreasing serotonin levels reduces the responsiveness of key parts of the amygdala, which dampens the expression of learned fear (Macedo et al., 2007). Buspirone must be taken daily, and it may take 2 weeks or more for symptoms of GAD to diminish and 6 weeks for the medication to attain its maximal effects.

Most people with GAD are also depressed, and buspirone only helps anxiety symptoms (Davidson, 2001). In contrast, the serotonin/norepinephrine reuptake inhibitor (SNRI) *venlafaxine* (Effexor) and certain selective serotonin reuptake inhibitors (SSRIs), such as *paroxetine* (Paxil) and *escitalopram* (Lexapro), appear to relieve both anxiety and depressive symptoms (Baldwin & Polkinghorn, 2005; Davidson et al., 1999). This is why an SNRI is considered the first-line medication for people with both GAD and depression, meaning that it is the medication that clinicians try first with these patients (unless there is a reason not to use it). However, when medication is the sole treatment and patients stop taking it, symptoms are likely to return. For this reason, medication may be used in conjunction with behavioral and cognitive methods.

Targeting Psychological Factors

Psychological treatments for GAD generally have several aims:

- to increase the person's sense of control over thoughts and worries,
- to allow the person to assess more accurately how likely and dangerous perceived threats actually are, and
- to decrease muscle tension.

Psychotherapy for GAD generally consists of behavioral and cognitive methods, which can successfully decrease symptoms (Borkovec & Ruscio, 2001; Cottraux, 2004; Durham et al., 2003).

Behavioral Methods

Behavioral methods to treat GAD focus on three main areas (Barlow, 2002a):

- awareness and control of breathing,
- awareness and control of muscle tension and relaxation, and
- elimination, reduction, or prevention of behaviors associated with worry.

Breathing retraining requires patients to become aware of their breathing and to try to control it by taking deep, relaxing breaths. Such breathing can help induce relaxation and provide a sense of coping (of doing something positive in response to worry).

Similarly, *muscle relaxation training* requires patients to become aware of early signs of muscle tension, a symptom of GAD, and then to relax those muscles. (However, it is important to note that not all people with GAD exhibit muscle tension; Conrad, Isaac, & Roth, 2008.) Patients can learn how to identify tense muscles and then relax them through standard relaxation techniques or *biofeedback* (see Chapter 4). When electrodes are attached to a targeted muscle or group of muscles, the patient can see on a monitor or hear from a speaker signals that indicate whether the monitored muscles are tense or relaxed. This feedback helps the patient learn how to detect and reduce the tension, eventually without relying on the feedback.

People with GAD often develop behaviors that are associated with their worries. For instance, a patient who worries that “something bad” may happen to her family may call home several times each day. By calling home and finding out that everyone is fine, she temporarily lessens her anxiety, thus (negatively) reinforcing the calling behavior. People with GAD do not naturally habituate to such anxiety; as they worry about one set of concerns, they get increasingly anxious until they shift the focus of their worry to another set of concerns, never becoming habituated to any specific set of concerns.

Exposure is one method used to eliminate or reduce symptoms associated with GAD. Exposure relies on the principle of habituation (see Chapter 4) and when used to treat GAD, patients undergo prolonged exposure to their worries. They are

asked to think about only one specific worry (this is the exposure) and to imagine their worst possible fears about the subject of that worry, such as the possible deaths of family members. Patients are asked to think about their worry continuously for about 30 minutes. After this half-hour of exposure, patients then list their rational responses to the worst outcomes they imagined. Patients' anxiety and level of worry should decrease both over the course of the session and across sessions. When patients can think about one set of concerns without much worry or anxiety, they move on to use the same procedure with another set of concerns (see Figure 7.4).

Figure 7.4

Worry exposure first involves evoking a particular worry as vividly as possible and trying to imagine the worst-case scenario related to that worry.

The patient then tries to stay focused on the single worry for about a half-hour; the patient should habituate to the anxiety caused by the worry.

Once the patient has habituated somewhat to the worry, the patient and therapist generate possible rational alternatives to the worst-case scenario.

After the patient has habituated to and developed a rational response to a particular worry, he or she is ready to go through the same process with a new, specific worry.

7.4 ► Worry Exposure

Source: Adapted from Brown, O'Leary, & Barlow, 1993.

Cognitive Methods

Cognitive methods for treating GAD focus on first helping patients to identify the thought patterns that are associated with their worries and anxieties and then helping them to use cognitive restructuring and other methods to prevent these thought patterns from spiraling out of control. The methods can also decrease the *intensity* of patients' responses to their thought patterns, so that they are less likely to develop symptoms. Specific cognitive methods include the following:

- *Psychoeducation* about the nature of worrying and GAD symptoms and available treatment options and their possible advantages and disadvantages.
- *Meditation*, which helps patients learn to “let go” of thoughts and reduce the time spent thinking about worries (Evans et al., 2008; Lehrer & Woolfolk, 1994; Miller, Fletcher, & Kabat-Zinn, 1995).
- *Self-monitoring*, which helps patients become aware of cues that lead to anxiety and worry. For instance, patients may be asked to complete a daily log about their worries, identifying events or stimuli that lead them to worry more or worry less.
- *Problem solving*, which involves teaching the patient to think about worries in very specific terms—rather than global ones—so that they can be addressed through cognitive restructuring. Here's an exchange between a therapist and a patient with GAD. The patient starts out talking about a night when sleep had been particularly elusive; the phone had rung at 11:30 P.M., but it was a wrong number. Near the end of the exchange, the therapist tries to engage the patient in problem solving.

Therapist: What did you think the call might be about?

Patient: Well, you know, bad news of some sort, someone dying or something like that. After my visit home this summer, I have often worried that my father is getting up there in years, he turned 55 in July, and, well, since I moved to Albany I haven't seen my folks nearly as much as I would have liked to.

Therapist: So, when the phone rang, you were worried that something may have happened with your father?

Patient: I don't think just then because I picked up the phone real fast, but the phone ringing kind of startled me. But after I hung up, I wondered why I was so anxious and I realized that I must have thought that something happened to him. Once I realized that, I was worried about him the rest of the night.

Therapist: If I recall from what you said before, he's in pretty good health, isn't he?

Patient: Yeah, he had a mole removed a while ago. Since he's worked outside all of his life, I worry that all that sun will have caused him to get skin cancer some day.

Therapist: What do you picture happening if your dad did pass away? [Note: Therapist attempts to help the patient frame the problem as a worst-case scenario; patient and therapist can then engage in problem solving.]

Patient: What do you mean? Do you mean what would I do?

(Brown, O'Leary & Barlow, 1993, p. 159)

- *Cognitive restructuring*, which involves helping the patient learn to identify and shift automatic, irrational thoughts related to worries (see the third panel in Figure 7.4). With the patient concerned about his father's health, the therapist could point out that the patient is using catastrophic thinking as well as overestimating the probability that something dire will occur (Brown, O'Leary & Barlow, 1993).

Targeting Social Factors

The neuropsychosocial approach leads us to notice whether certain kinds of treatments are available for particular disorders. For instance, at present, there are very few treatments for GAD that specifically target social factors.

Although CBT for GAD may be provided in a group format (Dugas et al., 2003), such groups seek to change thoughts, behaviors, and feelings; they do not directly focus on changing relationships, family dynamics, or other social factors. Similarly, family or couples therapy may be employed, but such treatment is usually a supplement to the primary treatment of medication or CBT.

FEEDBACK LOOPS IN TREATMENT: Generalized Anxiety Disorder

Muscle relaxation training involves increasing the patient's awareness of muscle tension (psychological factor) and then using techniques to decrease that tension; this process leads to neurological changes (neurological factor), particularly when it reduces stress and thereby decreases the levels of stress hormones. In turn, as other behavioral methods and cognitive methods (psychological factors) reduce worry and anxiety, the patient can devote his or her attention to other matters, including relationships and work (social factors). For instance, with A. H. (the woman in Case 7.1), treatment consisted of psychoeducation, self-monitoring, exposure, and cognitive restructuring. Successful treatment also affected social factors: Her children found her "less moody" and "more fun to be with" (Brown & Barlow, 1997, p. 15). Thus, when behavioral methods and cognitive methods are successful, the individual develops a sense of mastery of and control over worries and anxiety (which decreases anxiety even further), and social interactions reinforce new behaviors. Similarly, medication directly targets neurological factors, which in turn reduces the individual's worries and anxiety; he or she becomes less preoccupied with these concerns, which increases the ability to focus at work and in relationships. These feedback loops are illustrated in Figure 7.5.

Did Earl Campbell develop GAD? Although his worries may seem excessive and uncontrollable at times, they do not appear to have had the effects necessary for the diagnosis, such as muscle tension, irritability, or difficulty sleeping (Criterion C, Table 7.1). Any irritability or sleep problems he had are better explained as symptoms of another anxiety disorder—panic disorder, which we discuss in the following section.

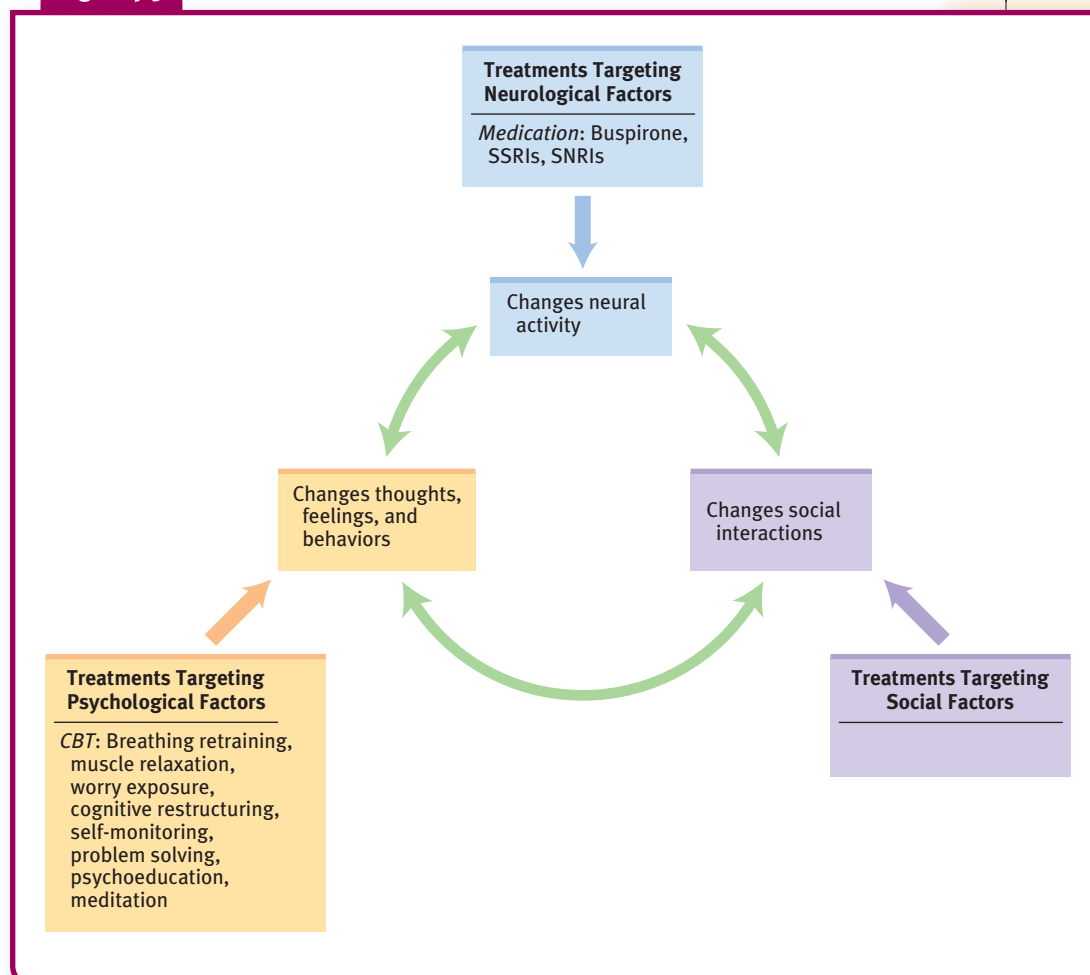

Figure 7.5

7.5 ► Feedback Loops in Treating Generalized Anxiety Disorder

Key Concepts and Facts About Generalized Anxiety Disorder

- Generalized anxiety disorder is marked by persistent uncontrollable worry about a number of events or activities that are not solely the focus of another Axis I disorder. Most people with GAD also have comorbid depression.
- Neurological factors associated with GAD include:
 - more gray and white matter in the areas of the brain related to hearing and language comprehension—the superior temporal gyrus—particularly in the right hemisphere. Moreover, unlike most other anxiety disorders, GAD is associated with *decreased* arousal because the parasympathetic nervous system is extremely responsive.
 - unusually strong activation in the right front lobe when viewing angry faces, which may be related to the operation of coping mechanisms;
 - abnormal activity of serotonin, dopamine, and other neurotransmitters, which in turn influences motivation, response to reward, and attention;
 - a genetic predisposition to become anxious and/or depressed. This predisposition, however, is not specific to GAD.
- Psychological factors that contribute to GAD include being hypervigilant for possible threats, a sense that the worrying is out of control, and the reinforcing experience that worrying prevents panic.
- Social factors that contribute to GAD include stressful life events, which can trigger the disorder.
- Treatments for GAD include:
 - medication (which targets neurological factors), such as buspirone or an SNRI or SSRI when depression is present as a comorbid disorder; and
 - CBT (which targets psychological factors), which may include breathing retraining, muscle relaxation training, worry exposure, cognitive restructuring, self-monitoring, problem solving, psychoeducation, and/or meditation. CBT may be employed in a group format.

Making a Diagnosis

- Reread Case 7.1 about A. H., and determine whether or not her symptoms meet the criteria for generalized anxiety disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Panic Disorder (With and Without Agoraphobia)

Earl Campbell's uncomfortable episodes of anxiety didn't stop:

The second night we were in the [new] house, I had my third episode. It felt just like the second one had. I was lying in bed watching television, and Reuna was sound asleep next to me. I was trying to relax and not think about my problem, but my problem was all I could think about. All of a sudden, my heart went crazy—pounding, pounding harder and harder. I thought it was going to leap right out of my chest. I sat up, struggling to regain my composure. It got worse. I couldn't breathe again.

(Campbell & Ruane, 1999, p. 92)

Campbell again thought he was having heart attack and that his life was ending. Campbell was having a panic attack. A **panic attack** is a specific period of intense dread, fear, or a sense of imminent doom, accompanied by physical symptoms of a pounding heart, shortness of breath, shakiness, and sweating.

The Panic Attack—A Key Ingredient of Panic Disorder

Some of the physical symptoms of a panic attack may resemble those associated with a heart attack—heart palpitations, shortness of breath, chest pain, and a feeling of choking or being smothered (see Table 7.3), which is why Earl Campbell mistook his panic attacks for heart attacks. In fact, emergency room staff have learned to look for evidence of panic attack when a patient arrives who purportedly has had a heart attack, as was the case with Campbell, who was brought to the hospital by ambulance after his second panic attack. During a panic attack, the symptoms generally begin quickly, peak after a few minutes, and disappear within an hour. As noted by Campbell, the symptoms of a panic attack can be frightening and extremely aversive.

In some cases, panic attacks are *cued*—they are associated with particular objects, situations, or sensations. Although panic attacks are occasionally cued by

Panic attack

A specific period of intense dread, fear, or a sense of imminent doom, accompanied by physical symptoms of a pounding heart, shortness of breath, shakiness, and sweating.

Table 7.3 ▶ DSM-IV-TR Criteria for a Panic Attack

A discrete period of intense fear or discomfort, in which at least four of the following symptoms develop abruptly and reach a peak within 10 minutes:

- | | |
|--|---|
| <ul style="list-style-type: none"> • palpitations, pounding heart, or accelerated heart rate • sweating • trembling or shaking • sensations of shortness of breath or smothering • feeling of choking • chest pain or discomfort • nausea or abdominal distress | <ul style="list-style-type: none"> • feeling dizzy, unsteady, lightheaded, or faint • derealization (feelings of unreality) or depersonalization (being detached from oneself) • fear of losing control or going crazy • fear of dying • paresthesias (numbness or tingling sensations) • chills or hot flushes |

a particular external stimulus (such as seeing a snake), they are more frequently cued by situations that are associated with internal sensations similar to panic. For example, grocery shopping in the winter—with the heat and stuffiness that comes from being under layers of clothing while inside of a store—may remind a person of sensations associated with a previous panic attack, which can lead to anxiety about having another panic attack. In other cases, panic attacks are *uncued*—they are spontaneous—they feel as though they come out of the blue, and are not associated with a particular object or situation. Panic attacks can occur at any time, even while sleeping (referred to as *nocturnal panic attacks*, which Campbell experienced). Infrequent panic attacks are not unusual; they affect 30% of adults at some point in their lives.

Recurrent panic attacks may interfere with daily life (for example, if they occur on a bus or at work) and cause the individual to leave the situation to return home or seek medical help. The symptoms of a panic attack are so unpleasant that people who suffer from this disorder may try to prevent another attack by avoiding environments and activities that increase their heart rates (hot places, crowded rooms, elevators, exercise, sex, mass transportation, or sporting events). They might even avoid leaving home (Bouton, Mineka, & Barlow, 2001).

What Is Panic Disorder?

Campbell describes *panic disorder*: “. . . the fear of having another panic attack, because the last thing in the world you want to face is one more of those horrible, frightening experiences. And the last thing you want to accept is the idea of living the rest of your life with panic. This condition caused me to shut myself up in the my house, where I would sit in the dark, frustrated, crying, afraid to go out. At one point, I even considered suicide” (Campbell & Ruane, 1999, p. ii).

To mental health clinicians, **panic disorder** is marked by frequent, unexpected panic attacks, along with fear of further attacks and possible restrictions of behavior in order to prevent such attacks (see Table 7.4). Note, however, that having panic attacks doesn’t necessarily indicate a panic disorder. Panic attacks are distinguished from panic disorder by the frequency and unpredictability of the attacks and the individual’s reaction to the attacks. Campbell’s life changed as a result of his efforts to prevent additional attacks: “I remember all the places I’ve had an attack, and I make a concerted effort to avoid those places” (Campbell & Ruane, 1999, p. 201). Table 7.5 lists additional facts about panic disorder, and Case 7.2 provides a glimpse of a woman who suffers from panic attacks.

Panic disorder

The anxiety disorder characterized by frequent, unexpected panic attacks, along with fear of further attacks and possible restrictions of behavior in order to prevent such attacks.

CASE 7.2 ► FROM THE OUTSIDE: Panic Disorder

S was a 28-year-old married woman with two children, aged 3 and 5 years. S had experienced her first panic attack approximately 1 year prior to the time of the initial assessment. Her father had died 3 months before her first panic attack; his death was unexpected, the result of a stroke. In addition to grieving for her father, S became extremely concerned about the possibility of herself having a stroke. S reported [that before her father's death, she'd never had a panic attack nor been concerned about her health.] Apparently, the loss of her father produced an abrupt change in the focus of her attention, and a cycle of anxiety began [which led to a heightened] awareness of the imminence of her own death, given that "nothing in life was predictable." . . . S became increasingly aware of different bodily sensations. Following her first panic attack, S was highly vigilant for tingling sensation in her scalp, pain around her eyes, and numbness in her arms and legs. She interpreted all of these symptoms as indicative of impending stroke. Moreover, because her concerns became more generalized, she began to fear any signs of impending panic, such as shortness of breath and palpitations.

Her concerns led to significant changes in her lifestyle [and she avoided] unstructured time in the event she might dwell on "how she felt" and, by so doing, panic. . . . S felt that her life revolved around preventing the experience of panic and stroke.

(Craske, Barlow, & Meadows, 2000, pp. 45–46)

Symptoms of panic disorder are similar across cultures, but in some cultures, the symptoms focus on fear of magic or witchcraft (American Psychiatric Association, 2000); in other cultures, the physical symptoms may be expressed differently. For example, among Cambodian refugees, symptoms of panic disorder include a fear that "wind-and-blood pressure" (referred to as *wind overload*) may increase to the point of bursting the neck area, and patients may complain of a sore neck, along with headache, blurry vision, and dizziness (Hinton, Um, & Ba, 2001).

In some cultures, people experience symptoms that are similar—but not identical—to the classic symptoms of a panic attack. In the Caribbean, Puerto Rico, and some areas of Latin America, an anxiety-related problem called *ataque de nervios* can occur (usually in women). The most common symptoms are uncontrollable screaming and crying attacks, together with palpitations, shaking, and numbness. An *ataque*

Table 7.4 ► DSM-IV-TR Diagnostic Criteria for Panic Disorder (Without Agoraphobia)

A. Both (1) and (2):

- (1) recurrent unexpected Panic Attacks
- (2) at least one of the attacks has been followed by 1 month (or more) of one (or more) of the following:
 - (a) persistent concern about having additional attacks
 - (b) worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, "going crazy")
 - (c) a significant change in behavior related to the attacks

B. Absence of Agoraphobia [discussed later in this section].

C. The Panic Attacks are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism).

D. The Panic Attacks are not better accounted for by another mental disorder, such as Social Phobia (e.g., occurring on exposure to feared social situations [discussed later in this chapter]), Specific Phobia (e.g., on exposure to a specific phobic situation [discussed later in this chapter]), Obsessive-Compulsive Disorder (e.g., on exposure to dirt in someone with an obsession about contamination [discussed later in this chapter]), Posttraumatic Stress Disorder (e.g., in response to stimuli associated with a severe stressor [discussed later in this chapter]), or Separation Anxiety Disorder (e.g., in response to being away from home or close relatives [Chapter 14]).

Table 7.5 ▶ Panic Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none"> Up to 3% of people worldwide will experience panic disorder at some point in their lives (Rouillon, 1997; Somers et al., 2006). However, 30% of people will experience at least one panic attack in their lives. Up to 60% of people seen by cardiologists have panic disorder.
Comorbidity
<ul style="list-style-type: none"> About 80% of people with panic disorder will have an additional Axis I disorder (Ozkan & Altindag, 2005). The two Axis I disorders mostly commonly associated with panic disorder are depression (up to 65% of cases) and substance abuse (up to 30% of cases) (Biederman et al., 2005; Keller & Hanks, 1994; Magee et al., 1996). Approximately 15–30% of those with panic disorder also have social phobia or GAD, and 2–20% have some other type of anxiety disorder (Goisman et al., 1995). Over a third of those with panic disorder also have a personality disorder—an Axis II disorder (Ozkan & Altindag, 2005).
Onset
<ul style="list-style-type: none"> Panic disorder is most likely to arise during two phases of life: the teenage years or the mid-30s.
Course
<ul style="list-style-type: none"> The frequency of panic attacks varies from person to person: <ul style="list-style-type: none"> Some people get panic attacks once a week for months, Others have attacks every day for a week. The frequency of panic attacks can vary over time: <ul style="list-style-type: none"> After having regular panic attacks, a person can experience weeks or even years with less frequent attacks or no attacks at all, Other patients come to have limited-symptom attacks—experiencing fewer than the minimum of four symptoms necessary for a diagnosis of panic attack (see Table 7.3), Some people have no change over time in the frequency of their attacks.
Gender Differences
<ul style="list-style-type: none"> Women are two to three times more likely than men to be diagnosed with panic disorder.
Cultural Differences
<ul style="list-style-type: none"> Symptoms of panic disorder are generally similar across cultures, although people in some cultures may experience or explain the symptoms differently, such as “wind overload” among the Khmer (Hinton et al., 2002, 2003).
Source: Unless otherwise noted, information in the table is from American Psychiatric Association, 2000.

de nervios differs from a panic attack not only in the specific symptoms experienced, but also because it usually is triggered by a specific upsetting event, such as a funeral or a family conflict. Panic attacks that are part of panic disorder tend not to have such an obvious situational trigger. Furthermore, people who have had an *ataque de nervios* are usually not worried about recurrences (Guarnaccia, 1997b; Salmán et al., 1997).

Panic disorder, as well as *ataque de nervios* and other anxiety disorders, is diagnosed in at least twice as often in women as in men (American Psychiatric Association, 2000). A cultural explanation for this gender difference is that men may be less likely to report symptoms of anxiety or panic because they perceive them as inconsistent with how men are “supposed” to behave in their culture (Ginsburg & Silverman, 2000).

In short, panic disorder has a core of common symptoms across the world, centering on frequent, unexpected panic attacks and fear of further attacks, but culture does affect the specifics.

What Is Agoraphobia?

After Campbell’s first panic attack, he refused to go out:

. . . I knew I could not set foot outside my house. Until I learned what was wrong with me, the only place I would go was to a doctor’s office or a hospital. . . . Reuna thought that was part of my problem. I was shutting myself off from the world. I was going to sleep very late, waking up at noon, spending the whole day in bed. She said I needed to pull my life back together or I would never get well. . . . The thing she failed to understand was the predicament I would be placing myself in if I did go out. What if I had another attack? What if it happened while I was in church? Or while I was walking down the aisle of a crowded grocery store? What would I do? How could I deal with the humiliation that such a loss of control would bring?
(Campbell & Ruane, 1999, pp. 93–94)

Campbell had developed *agoraphobia*.

Agoraphobia (which literally means “fear of the marketplace”) refers to the persistent avoidance of situations that might trigger panic symptoms or from which escape would be difficult. Moreover, many patients with agoraphobia may avoid places in which it would be embarrassing or hard to obtain help in case of a panic attack. For these reasons, tunnels, bridges, crowded theaters, and highways are typically avoided or entered with difficulty by people with agoraphobia.

Some people have agoraphobia without having panic attacks, but it is not common. These people avoid situations where they fear they might lose control of themselves for some other reason (such as incontinence) or where they fear they may experience symptoms that are less severe or numerous than the criteria for a panic attack (listed in Table 7.3). For instance, they might avoid types of situations that have, in the past, triggered palpitations and nausea (but experience less than the minimum of four symptoms necessary for a panic attack). However, people who only avoid particular kinds of stimuli (*only* bridges or *only* parties) are not diagnosed with agoraphobia, which is a more general pattern of avoiding many kinds of environments or situations. Table 7.6 lists the criteria for agoraphobia, but note that it is not a separate DSM-IV-TR diagnosis. A patient with agoraphobia will be

Table 7.6 ▶ DSM-IV-TR Criteria for Agoraphobia

A. Anxiety about being in places or situations from which escape might be difficult (or embarrassing) or in which help may not be available in the event of having an unexpected or situationally predisposed panic attack or panic-like symptoms. Agoraphobic fears typically involve characteristic clusters of situations that include being outside the home alone; being in a crowd or standing in a line; being on a bridge; and traveling in a bus, train, or automobile.

Note: Consider the diagnosis of Specific Phobia [discussed later in this chapter] if the avoidance is limited to one or only a few specific situations, or Social Phobia [discussed later in this chapter] if the avoidance is limited to social situations.

B. The situations are avoided (e.g., travel is restricted) or else are endured with marked distress or with anxiety about having a panic attack or panic-like symptoms, or require the presence of a companion.

C. The anxiety or phobic avoidance is not better accounted for by another mental disorder, such as Social Phobia (e.g., avoidance limited to social situations because of fear of embarrassment), Specific Phobia (e.g., avoidance limited to a single situation like elevators), Obsessive-Compulsive Disorder (e.g., avoidance of dirt in someone with an obsession about contamination), Posttraumatic Stress Disorder (e.g., avoidance of stimuli associated with a severe stressor [all disorders discussed later in this chapter], or separation anxiety disorder (e.g., avoidance of leaving home or relatives [discussed in Chapter 14]).

Agoraphobia

The persistent avoidance of situations that might trigger panic symptoms or from which escape would be difficult.

Agoraphobia is not a separate DSM-IV-TR disorder. Patients who meet the criteria for agoraphobia are diagnosed with either panic disorder with agoraphobia or agoraphobia without history of panic disorder, depending on the presence or absence of panic disorder.

diagnosed with either *panic disorder with agoraphobia* (if he or she also has panic disorder) or *agoraphobia without history of panic disorder* (if he or she had never had panic disorder). Between one third and one half of those with panic disorder also have agoraphobia. Some researchers suggest that agoraphobia—with no reference to panic disorder—should be a disorder in future diagnostic manuals (Bienvenu et al., 2006). Shirley B., in Case 7.3, suffered from symptoms of agoraphobia.

CASE 7.3 ► FROM THE INSIDE: Agoraphobia

“The Story of an Agoraphobic” by Shirley B.

As I am writing this I am a 46-year-old recovering agoraphobic. Whew! I never thought I could say that, let alone write it. But three weeks after I first admitted it in therapy, I crossed the street eight times on my own. Some people would say “That is no big deal.” No, it’s not a big deal—it’s a MIRACLE! I wanted to shout, “Hello again world, I’m back. It’s me, Shirley B.!!!” Living is what I do now. Not as fully as I plan to, but it is so much more than just being. . . .

There isn’t much I can say about how I became agoraphobic. I just slipped a little day by day. . . . My daughter Nadeen was always by my side on those rare occasions when I ventured outside, forced to leave my home when I needed medical attention. In the past my fear kept me at home with all sorts of physical pains and ailments, as horrific as the pain was, the pain of facing the outside world was greater. When I had two abscessed teeth and my jaw was swollen to twice its normal size I was in such excruciating pain that I had to go to the dentist. So with my legs wobbling, my heart pounding, my hands sweating, and my throat choking, to the dentist I went. After examining my x-rays, the dentist said he wouldn’t be able to do anything with my teeth because they were so infected, he prescribed medication for the pain and infection and said that I must return in ten days, not in two years. I felt as though those ten days were a countdown to my own execution. Each day passed at lightning speed—like a clock ticking away. The fear grew stronger and stronger. I had to walk around with my hand on my heart to keep it from jumping so hard, as if I were pledging allegiance, which I was—to my fears and phobia. I asked God to please give me strength to go back to the dentist. When the day came, I knew that my preparations would take me a little over four hours. I had to leave time, not just to bathe and dress, but to debate with myself about going.

Source: Anxiety Disorders Association of America.

People with extreme agoraphobia cannot function normally in daily life. They are totally housebound, too crippled by panic and fear to go to work, the supermarket, or the doctor. Others with agoraphobia are able to function better than Shirley B. and can enter many situations without triggering a panic attack. Relying on a friend or family member (often referred to as a “safe” person), such as Shirley’s daughter Nadeen, can help the sufferer enter feared situations that otherwise might be avoided.

When agoraphobia develops, it usually does so within the first year of recurrent panic attacks (American Psychiatric Association, 2000). For some individuals, as panic attacks decrease, agoraphobia decreases; for others, there is no such relationship. Because people with agoraphobia avoid situations that are associated with past panic attacks, they do not learn that they can be in such situations and not have a panic attack.

Understanding Panic Disorder and Agoraphobia

“I still don’t know what triggers a panic attack, but I can tell anyone reading this who has never experienced one that it is a devastating experience. I don’t have many attacks these days, but when they come, they come hard and bring me to my knees. An attack may hit me on a day when I’m feeling relaxed and happy. That’s when I think, ‘Why me?’ ‘Why today?’” (Campbell & Ruane, 1999, p. 151). Let’s use the neuropsychosocial approach to address Campbell’s question about why panic disorder and agoraphobia arise and are maintained. Each type of factor makes an important and unique contribution.

Neurological Factors

Brain systems, neural communication, and genetics contribute to panic disorder and agoraphobia. Specifically, these three types of neurological factors appear to give rise to a heightened sensitivity to breathing changes.

Brain Systems

One key to explaining panic attacks came after researchers discovered that they could induce attacks in the laboratory. Patients who had had panic attacks volunteered to hyperventilate (that is, to breathe in rapid, short pants, decreasing carbon dioxide levels in the blood), which can trigger panic attacks. Moreover, researchers found that injections of some medically safe substances, such as sodium lactate (a salt produced in sweat) and caffeine, produced attacks—but only in people who have panic disorder (Nutt & Lawson, 1992; Pitts & McClure, 1967). Why do these substances induce panic attacks? One possibility is that they trigger a brain mechanism that warns us when we are suffocating (Klein, 1993). According to this theory, the brains of people who experience panic attacks have a low threshold for detecting decreased oxygen in the blood (Beck, Ohtake, & Shipherd, 1999; Papp, Klein, & Gorman, 1993; Papp et al., 1997).

As predicted by this theory, patients with panic disorder cannot hold their breath as long as control participants can (Asmundson & Stein, 1994). When triggered, the neural mechanism not only produces panic, but also leads to hyperventilation and a strong sense of needing to escape. The need to escape is consistent with the finding that the right frontal lobe is activated more than the left when people with panic disorder see stimuli that are likely to induce panic symptoms, such as a photograph of an emergency situation (Wiedemann et al., 1999). Why? Researchers have documented that a key part of the right frontal lobe is more strongly activated when people experience withdrawal emotions (such as fear) than when feeling approach emotions (such as joy) (Davidson, 1992). In addition, as noted earlier, the frontal lobes have direct connections to the amygdala (a subcortical structure that is involved in feeling strong emotions) and to the hypothalamus (a subcortical structure that is involved in the fight-or-flight response) (Gabbott et al., 2005; Ghashghaei & Barbas, 2002; Teves et al., 2004). Indeed, the frontal lobe helps to regulate the limbic system and hence plays a central role in both the triggering and modulating emotions (LeDoux, 1996, 2000).

Thus, the data suggest that withdrawal emotions—which prompt escape from a situation—are relatively easily induced in people with panic attacks. These emotions may be triggered by the sense of impending suffocation, which in turn may activate the limbic system and autonomic nervous system, as in the fight-or-flight response. However, research findings do not show that all panic attacks are a result of a suffocation reaction or that all such attacks are accompanied by activation of withdrawal mechanisms in the brain. In fact, researchers have documented two types of panic disorder, one based on a lower threshold for detecting suffocation (Abrams, Rassovsky & Kushner, 2006) and one based on learning (Acheson et al., 2007).

Neural Communication

Researchers have been investigating the role of neurotransmitters and neuromodulators in giving rise to panic disorder. One key neurotransmitter is norepinephrine, too much of which is apparently produced in people who have anxiety disorders (Nutt & Lawson, 1992). To explain this finding, some researchers have focused on a small subcortical structure called the *locus coeruleus*, which is located in the brainstem. The locus coeruleus produces norepinephrine, and some have theorized that it is too sensitive in people with panic disorder (Gorman et al., 1989) and thus may produce too much norepinephrine. The locus coeruleus and norepinephrine are important because they are central to the body's "alarm system," which causes the fight-or-flight response (including faster breathing, increased heart rate, and sweating), which can occur at times of panic. However, the picture is complicated by the fact that panic attacks do not increase levels of stress-related hormones

(e.g., cortisol), which usually accompany the fight-or-flight response (Otte et al., 2002). Thus, panic is not the same thing as the ordinary stress response, although it may arise in part through some mechanisms that are also involved in helping us respond to emergencies.

Finally, serotonin may also play a role in panic disorder; this idea is supported by the fact that SSRIs can reduce the frequency and intensity of panic attacks (DeVane, 1997). Serotonin affects the locus coeruleus in complex ways, and it may exert its effects on panic attacks indirectly, by altering the operation of this brain structure (Bell & Nutt, 1998).

Genetics

Genetic factors appear to play a role in the emergence of panic disorder. In fact, first-degree biological relatives of people with panic disorder are up to eight times more likely to develop the disorder than are control participants, and up to 20 times more likely to do so if the relative developed it before 20 years of age (Crowe et al., 1983; Torgersen, 1983; van den Heuvel et al., 2000). Twin studies have yielded similar results by examining concordance rates; a **concordance rate** is the probability that both twins will have a characteristic or disorder, given that one of them has it. The concordance rate in pairs of female identical (monzygotic) twins is approximately 24%, in contrast to 11% for pairs of fraternal (dizygotic) twins (Kendler et al., 1993). However, the genetic predisposition is not specific for panic disorder. One twin study revealed that 20% of the heritability of panic disorder arises from factors that also lead to GAD and PTSD and another 20% is specific to panic disorder; the remaining 60% of the heritability was accounted for by nonshared environmental factors, such as particular traumatic experiences (Chantarujikapong et al., 2001). Earl Campbell wasn't the only one in his family to experience anxiety: His paternal aunt, maternal uncle and two of his sisters had significant anxiety symptoms.

Psychological Factors

We saw earlier that not all cases of panic disorder are related to a person's threshold for detecting suffocation—some cases of panic disorder arise from learning. Thus, behavioral and cognitive theories can also help us understand how panic disorder and agoraphobia arise and are perpetuated: People come to associate certain stimuli with the sensations of panic, and then develop maladaptive beliefs about those stimuli and the sensations that are related to anxiety and panic.

Learning: An Alarm Going Off

Learning theory offers one possible explanation for panic disorder. Initially, a person may have had a first panic attack in response to a stressful or dangerous life event (a *true alarm*). This experience produces conditioning, whereby the initial bodily sensations of panic (such as increased heart rate or sweaty palms) become *false alarms* associated with panic attacks. Thus, the individual comes to fear those *interoceptive cues* (that is, cues received from the interior of the body) or the external environment in which they had the panic attack. As these normal sensations that are part of the fight-or-flight response come to be associated with subsequent panic attacks, the bodily sensations of arousal themselves come to *elicit* panic attacks (*learned alarms*). The person then develops a *fear of fear*—a fear that the arousal symptoms of fear will lead to a panic attack (Goldstein & Chambless, 1978), much as S did in Case 7.2. Earl Campbell described his fear of fear: “Living with the thought that at any moment you may have to go through another attack is horrible. It creates an entirely new kind of anxiety” (Campbell & Ruane, 1999, p. 115). After developing this fear of fear, the person tries to avoid behaviors or situations where such sensations might occur (Mowrer, 1947; White & Barlow, 2002).

Concordance rate

The probability that both twins will have a characteristic or disorder, given that one of them has it.

People whose hearts sometimes beat too quickly can be treated with a device implanted under the skin that shocks the heart, which causes it to beat at a normal speed again. However, the shocks can be uncomfortable and alarming. Research suggests that people who receive more frequent and intense shocks are more likely to develop panic disorder, which arises as a conditioned fear in response to the automatic shocks (Godemann et al., 2001).

Cognitive Explanations: Catastrophic Thinking and Anxiety Sensitivity

Cognitive theories, which focus on how a person *interprets* and then responds to alarm signals from the body, offer another possible explanation for panic disorder. People with panic disorder may misinterpret normal bodily sensations as indicating catastrophic effects (Salkovskis, 1988), which is referred to as *catastrophic thinking*. In essence, these interpretations can turn a panic attack into panic disorder. For instance, an increased heart rate may be (mis)interpreted as a signal of an impending heart attack. Such thoughts (“I’m going to have a heart attack”) are frightening, and the fright increases autonomic arousal (faster and shallower breathing, sweating, increased heart rate), which then leads to more anxiety about a catastrophic bodily problem, more vigilance for changes in the body, and—as a result of all this anxiety and vigilance—more changes in the body. This process becomes a vicious cycle.

Evidence for this cognitive explanation comes from laboratory studies: Reading pairs of words that relate both to the body and catastrophic states or events (such as the words *breathless* and *suffocate*) increases the probability that a person who has had panic attacks in the past will have a panic attack again (Clark et al., 1988). Moreover, cognitive therapy that reduces the sort of automatic thoughts that lead to the vicious cycle can reduce symptoms of panic disorder (Beck & Emery, 1985; Clark et al., 1994). However, at least some people have panic attacks that are not a result of catastrophic thoughts, at least not conscious ones (Kenardy et al., 1992; Kenardy & Taylor, 1999).

A tendency toward catastrophic thinking is related to *anxiety sensitivity*, which is a tendency to fear bodily sensations that are related to anxiety, along with the belief that such sensations indicate that harmful consequences will follow (McNally, 1994; Reiss, 1991; Reiss & McNally, 1985; Schmidt, Lerew, & Jackson, 1997). For example, a person with high anxiety sensitivity is likely to believe—or fear—that an irregular heartbeat indicates a heart problem or that shortness of breath signals being suffocated. People with high anxiety sensitivity tend to know what has caused their bodily symptoms—for instance, that exercise caused a faster heart rate—but they become afraid anyway, believing that danger is indicated, even if it is not an immediate danger (Bouton, Mineka, & Barlow, 2001; Brown et al., 2003).

Many researchers view anxiety sensitivity and being prone to anxiety as enduring traits that leave individuals more vulnerable to develop panic disorder. One bit of evidence came from a study that followed first-year Air Force Academy cadets who were enrolled in a 5-week basic training course—training that is both physically and psychologically stressful. Those cadets who had more anxiety sensitivity at the beginning of training were the ones who were likely to develop spontaneous panic attacks later. This finding suggests that the mental stressors of basic training,

Researchers have shown that the mental stressors of basic military training are more challenging to people with preexisting anxiety sensitivity.

U.S. Air Force Academy

over and above the physical ones, were more challenging to people with preexisting anxiety sensitivity (Schmidt, Lerew, & Jackson, 1997). (Note, however, that this study examined spontaneous panic attacks, not panic disorder.)

Cognitive explanations can also explain nocturnal panic attacks. Nocturnal panic attacks occur in the first few hours of sleep during the transition into the stage of slow-wave (deep) sleep (Bouton, Mineka, & Barlow, 2001); they do not occur during REM sleep—the stage of sleep when rapid eye movements occur and during which most dreaming occurs. Thus, nocturnal panic attacks are not associated with dreams (or nightmares). What might cause these nighttime panic attacks? A cognitive explanation focuses on the individual's hypervigilance for bodily changes—such as alterations in breathing patterns—during sleep, as might occur during the transition to slow-wave sleep (Barlow, 2002b; Craske & Rowe, 1997). Support for this explanation comes from the finding that patients who experience nocturnal panic attacks report more breathing-related symptoms than do patients whose panic attacks occur solely while they are awake (Sarísoy et al., 2008).

Social Factors: Stressors, “Safe” People, and a Sign of the Times

Evidence suggests that social stressors contribute to panic disorder: People with panic disorder tend to have had a higher than average number of such stressful events during childhood and adolescence (Horesh et al., 1997). Moreover, 80% of people with panic disorder reported that the disorder developed after a stressful life event.

Social factors are often related to the ways patients cope with agoraphobia. The presence of a close relative or friend—a “safe person”—can help decrease catastrophic thinking and panicking when a person with agoraphobia feels anxious. The safe person can also decrease the sufferer's arousal (Carter et al., 1995). Although a safe person can make it possible for the patient with agoraphobia to go into situations that he or she wouldn't enter alone, reliance on a safe person can end up perpetuating the disorder: By venturing into anxiety-inducing situations only when a safe person is around, the patient never habituates to his or her anxiety symptoms. Campbell describes his feelings about being alone versus having another person with him: “I'm still afraid to be alone for long stretches of time: my fear is that I'll have an attack, no one will be there to help me, and I'll die. But because I used to enjoy spending time alone, I push that envelope hard” (Campbell & Ruane, 1999, p. 197).

Cultural factors can influence whether people develop panic disorder, perhaps through culture's influence on personality traits. Consider that over the last five decades, increasing numbers of Americans have developed the personality trait of anxiety-proneness (Spielberger & Rickman, 1990). The average child today scores higher on measures of this trait than did children who received psychiatric diagnoses in the 1950s (Twenge, 2000)! Specifically, the average anxiety score for children with psychological problems in 1957 was somewhat lower than the average anxiety score for children *without* psychological problem in the 1980s. The higher baseline level of anxiety in the United States may be a result of greater dangers in the environment—such as higher crime rates, new threats of terrorism, and new concerns about food safety.

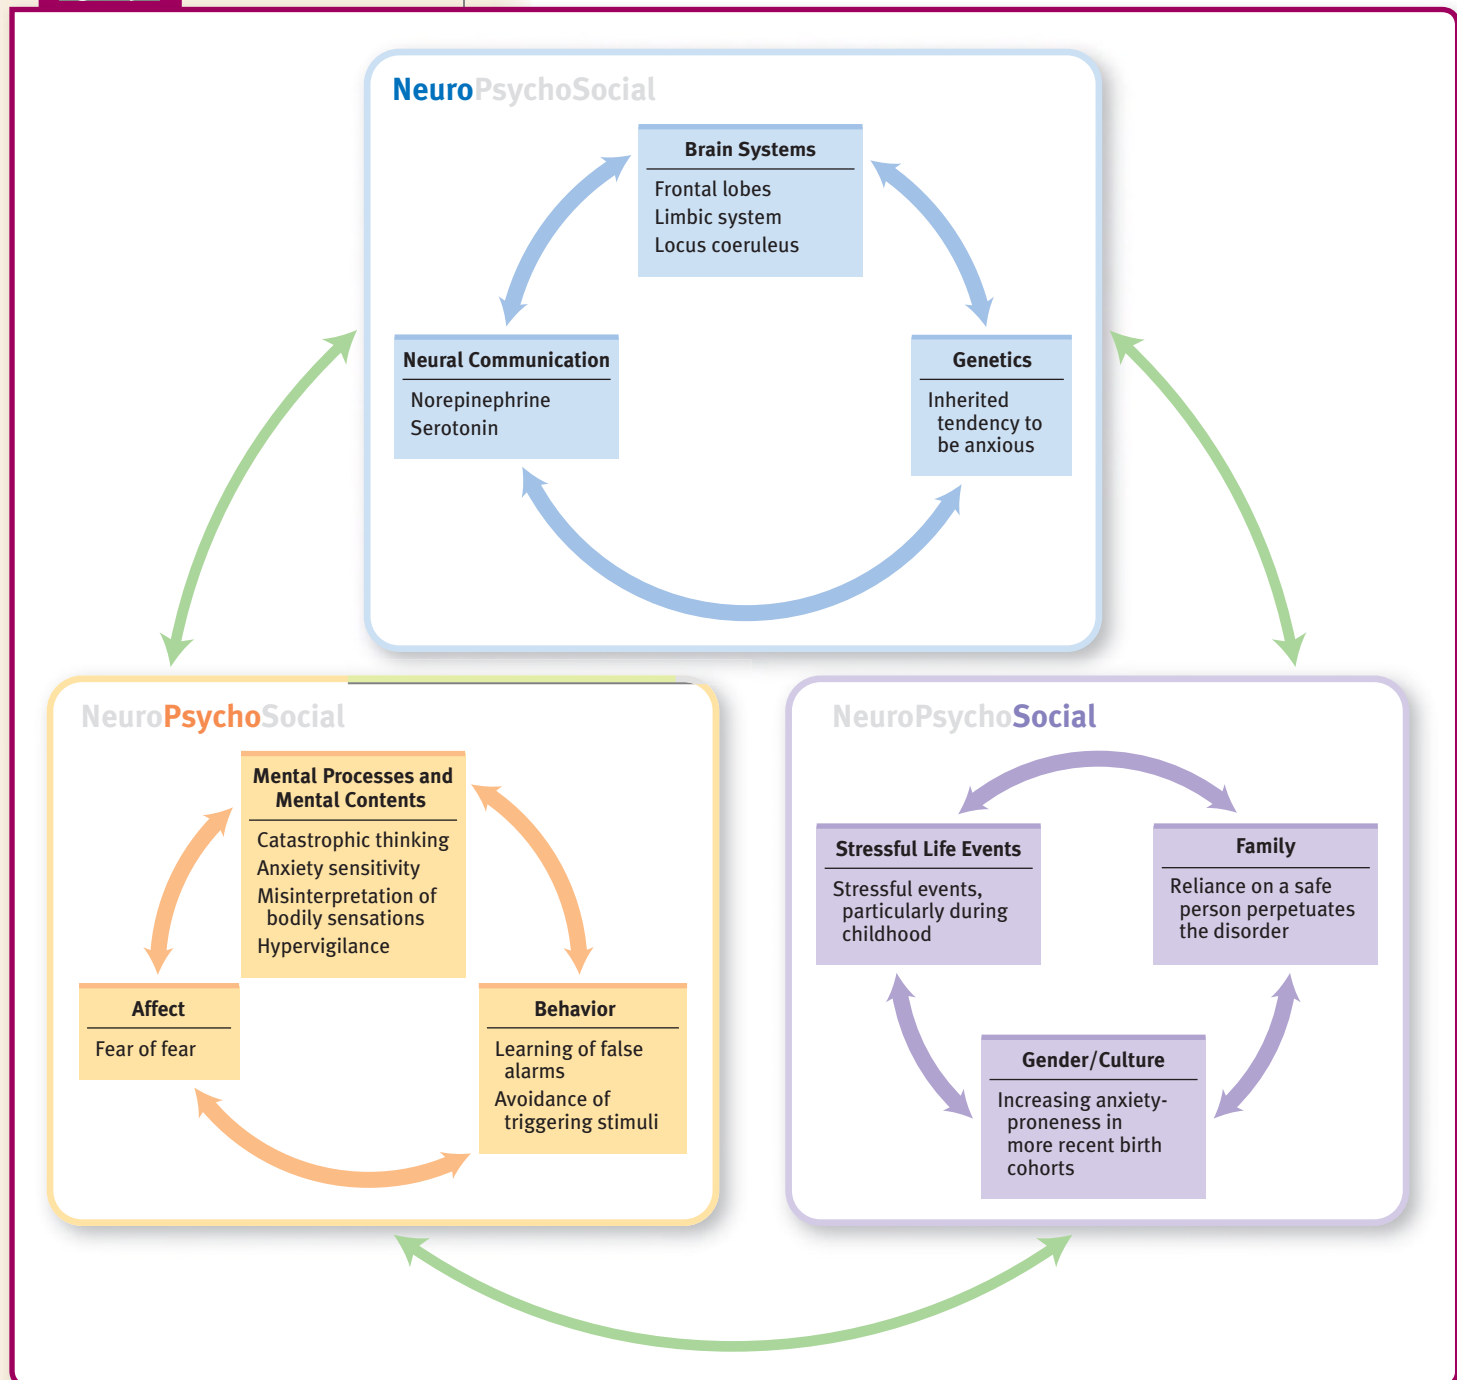

FEEDBACK LOOPS IN ACTION: Understanding Panic Disorder

Cognitive explanations of panic disorder can help show how a few panic attacks can progress to panic disorder, but not everyone who has panic attacks develops panic disorder. It is only when neurological and psychological factors interact with bodily states that panic disorder develops (Bouton, Mineka, & Barlow, 2001). Cognitive processes such as catastrophic thinking and anxiety sensitivity (psychological factors) are triggered, in part, by environmental and social stressors (social factors). Indeed, such stressors may lead an individual to be aroused (neurological factor), but he or she then misinterprets the cause of this arousal (psychological factor). This misinterpretation may increase the arousal (Wilkinson et al., 1998), making it more likely that symptoms of panic—rapid heartbeat or shallow breathing—will follow.

For example, a man's argument with his wife might arouse his anger and increase his breathing rate. Breathing faster results in a lower carbon dioxide level in the blood, which then leads the blood vessels to constrict—which means less oxygen throughout the brain and body; the ensuing physical sensations (such as light-headedness) may be misinterpreted as the early stages of suffocation, leading the man to panic (Coplan et al., 1998). This is how such physical changes can serve as a false alarm (Beck, 1976). After many false alarms, the associated sensations may become learned alarms and trigger panic in the absence of a social stressor (Barlow, 1988). Also, this man may become hypervigilant for alarm signals of panic attacks,

Figure 7.6

leading to anticipatory anxiety. In turn, this anxiety increases activity in his sympathetic nervous system, which is what causes the breathing and heart rate changes that he feared. In this way, the man may trigger his own panic attack. Figure 7.6 illustrates these three factors and their feedback loops.

Treating Panic Disorder and Agoraphobia

Earl Campbell received treatment for his panic disorder—medication, cognitive-behavior therapy (CBT), and social support—which targeted all three types of neuropsychosocial factors. Let's examine the various types of treatments commonly used for panic disorder.

Targeting Neurological Factors: Medication

To treat panic disorder, a psychiatrist or another type of health care provider licensed to prescribe medication may recommend an antidepressant or a benzodiazepine. Benzodiazepines are prescribed as a short-term remedy; the benzodiazepines *alprazolam* (Xanax) and *clonazepam* (Klonopin) affect the targeted symptoms within 36 hours, and they need not be taken regularly. One of these drugs might be prescribed during a short but especially stressful period. Side effects of benzodiazepines mainly include drowsiness and slowed reaction times, and patients can suffer withdrawal or develop tolerance to the medications when they are taken for an extended period of time (see Chapter 4). For these reasons, an antidepressant such as an SNRI, an SSRI, or a TCA (tricyclic antidepressant) such as *clomipramine* may be a better long-term medication. These medications can take up to 10 days to have an effect and may be prescribed at a lower dose than is usual for depression (Gorman & Kent, 1999; Kasper & Resinger, 2001). After Campbell's panic attacks were diagnosed, he initially relied on medication as his sole treatment; like most people, though, when he stopped taking the medication or forgot to take a pill, his symptoms returned. Such recurrences motivated him to make use of other types of treatments.

Targeting Psychological Factors

CBT is the first-line treatment for panic disorder because it has the most enduring beneficial effects of any treatment (Cloos, 2005). In fact, patients with either type of panic disorder (that arising primarily because of learning or that arising primarily through a lower threshold for detecting suffocation) profit to equal degrees from CBT (Taylor, Woody, et al., 1996). Moreover, CBT methods can even be effective in a self-help format, with minimal therapist contact (Carlbring & Andersson, 2006; Carlbring et al., 2005).

Effective CBT methods can emphasize either the behavioral or the cognitive aspects of change. Specifically, as discussed in the following sections, behavioral methods focus on the bodily signals of arousal and panic and on the avoidance behaviors, whereas cognitive methods focus on the misappraisal of bodily sensations and on the mistaken inferences about them. A meta-analysis of the effects of treatment for panic disorder that combined behavioral and cognitive methods found that over half of patients who completed treatment improved and remained improved 2 years later (Westen & Morrison, 2001).

Behavioral Methods: Relaxation Training, Breathing Retraining, and Exposure

For people with panic disorder, any bodily arousal can lead to a fight-or-flight response. To help counter this excessive response to arousal, therapists may teach patients breathing retraining and relaxation techniques to stop the progression from bodily arousal to panic attack and to increase a sense of control over bodily sensations. Campbell reported how he learned to take “long deep breaths and relax my body completely when panic struck. This is very difficult; at first I didn't believe I could do it. I somehow had to convince myself that the attack was not really happening. I had to fight it off by relaxing myself” (Campbell & Ruane, 1999, p. 119).

Other behavioral methods, such as exposure, focus on the patient's tendency to avoid activities that produce certain bodily sensations (such as not exercising in

In vivo exposure

The behavioral therapy method that consists of direct exposure to a feared or avoided situation or stimulus.

Interoceptive exposure

The behavioral therapy method in which patients intentionally elicit the bodily sensations associated with panic so that they can habituate to those sensations and not respond with fear.

order to prevent an increased heart rate) or to avoid situations associated with panic attacks (such as crowded theaters). Campbell, prior to his panic attacks, would jog 4–5 miles a day, but he stopped after his first panic attack: “I was afraid to go outside, afraid of having an attack right there on the street” (Campbell & Ruane, 1999, p. 108). Once he learned about panic disorder and how to combat it, he challenged himself to resume jogging. He began by walking alone down the block. Each day he went for a longer walk, and then he gradually started running.

Exposure for patients with agoraphobia addresses the particular situations they try to avoid. At the beginning of exposure treatment, patients may use *imaginal exposure*, exposure to mental images of the fear-inducing stimuli, progressing from least to most anxiety-inducing situations. They may then switch to **in vivo exposure**—direct exposure to the feared or avoided situation or stimulus (Barlow, Esler, & Vitali, 1998). The therapist or another person may accompany the patient on the first few in vivo exposures, or the patient may decide to have the experience alone. Not all patients, however, are willing or able to go through such exposure therapy; dropout rates have ranged from 3% to 25% (Chambless & Gillis, 1994; van Balkom et al., 1997). Of those patients who do undergo exposure treatment, 60–75% improve, and are still improved at follow-up 6–15 months later (Barlow, Esler, & Vitali, 1998). However, some patients continue to have residual symptoms of panic or avoidance, even though the treatment is largely successful.

To decrease a patient’s reaction to bodily sensations associated with panic, behavioral therapists may use **interoceptive exposure**: They have the patient intentionally elicit the bodily sensations associated with panic so that he or she can habituate to those sensations and not respond with fear. During exposure to interoceptive cues, patients are asked to behave in ways that induce the long-feared sensation, such as spinning around to the point of dizziness or intentionally hyperventilating (see Table 7.7 for a more extensive list). Within approximately 30 minutes, the bodily arousal subsides. This procedure allows patients to learn that the bodily sensations pass and no harm befalls them. Because patients had previously avoided activities that were associated with the sensations, they never got to see (and believe) that such sensations did not lead to a heart attack or suffocation.

Cognitive Methods: Psychoeducation and Cognitive Restructuring

Cognitive methods for panic disorder help the patient to recognize misappraisals of bodily symptoms and to learn to correct mistaken inferences about such symptoms. First, psychoeducation for people with panic disorder involves helping them to understand how their physical sensations are symptoms of panic and not of a heart attack or some other harmful medical situation. The therapist describes the biology of panic and explains how catastrophic thinking and anxiety sensitivity can lead panic attacks to develop into panic disorder. Campbell read a pamphlet about panic disorder that described his symptoms perfectly. Having learned about the disorder in this way, he was better able to handle future panic attacks: “One of the most important things I have learned about my panic disorder over the years is that although my heart may be racing and I may feel like I’m having a heart attack, I know that I’m not. And I know it’s going to stop” (Campbell & Ruane, 1999, p. 204).

Second, cognitive restructuring is then used to transform the patient’s initial frightened thoughts of a medical crisis into more realistic thoughts, identifying the symptoms of panic, which may be uncomfortable but do not indicate danger (Beck et al., 1979). For instance, a therapist helps a patient identify the automatic negative thought about bodily arousal (“I won’t be able to breathe . . . I’ll pass out”) and then challenges the patient about the belief: Was the patient truly unable to breathe, or was breathing only difficult? Has the patient fainted before? In this way, each of the patient’s automatic negative thoughts related to panic sensations are challenged and thereby reduced. Learning to interpret correctly both internal and external events can play a key role in preventing panic attacks that occur when a person experiences symptoms of suffocation (Clark, 1986; Taylor & Rachman, 1994).

Table 7.7 ▶ Interoceptive Exposure Exercises for Treatment of Panic Disorder

Exercise	Duration (seconds)	Sensation intensity (0–8)	Anxiety (0–8)	Similarity (0–8)
Shake head from side to side	30			
Place head between legs and then lift	30			
Run on spot	60			
Hold breath	30, or as long as possible			
Completely tense body muscles	60, or as long as possible			
Spin in swivel chair	60			
Hyperventilate	60			
Breathe through narrow straw	120			
Stare at spot on wall or own mirror image	90			

Source: Craske & Barlow, 1993, Table 1.4, p. 36. Copyright 1993 by Guilford Publications, Inc. For more information see the Permissions section.

People receiving interoceptive exposure perform each of the exercises listed in this table for the indicated duration; such exercises are likely to elicit sensations typically associated with panic. After each exercise, they rate how intense the sensations were, their level of anxiety while doing the exercise, and how similar the sensations were to panic symptoms.

Targeting Social Factors: Group and Couples Therapy

Therapy groups (either self-help or conducted by a therapist) that focus specifically on panic disorder and agoraphobia can be a helpful addition to a treatment program (Galassi et al., 2007). Meeting with others who have similar difficulties and sharing experiences can help to decrease a patient's sense of isolation and shame. Moreover, couples or family therapy may be appropriate when a partner or other family member has been the safe person; as the patient gets better, he or she may rely less on that person, which can affect their relationship. In some cases, the patient's increasing independence is satisfying for everyone; but if the safe person has found satisfaction in tending to the patient, the patient's increased independence can be a stressful transition for that person. For Shirley B. (see Case 7.3), her relationship with her daughter Nadeen would undoubtedly change as her agoraphobia diminishes, because she will no longer need Nadeen to accompany her on excursions out of the house. The particular ways their relationship changes will depend on how each of them views Shirley's new independence.

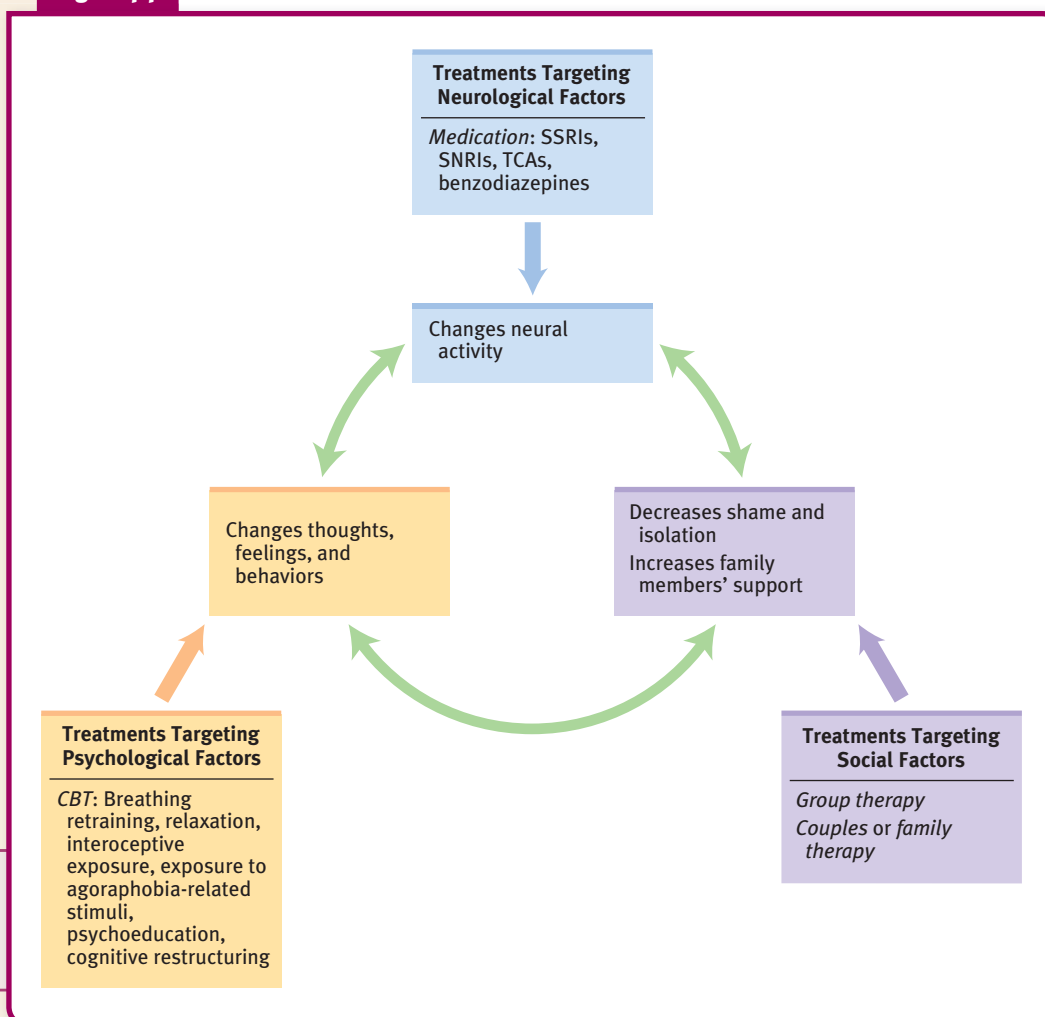

Family members and friends can also be great sources of support, as Campbell noted: "When I'm traveling, my schedule frequently becomes so hectic that I get a bit run-down. Then, I can usually feel the panic sneaking up on me, and I'll pick up the phone right away to call Reuna. Just as it does at home, on the road it tends to attack me in the middle of the night" (Campbell & Ruane, 1999, p. 120). Reuna reminds him to take deep breaths and helps him get through it. He also remembered that, "I'd made one of my biggest steps towards recovery the day I called Janice [his assistant] into my office and exposed my illness to her. I strongly encourage anyone suffering from panic or anxiety to do the same. Start with a close friend you can trust completely, tell that person about your condition, and ask for support. Then do the same with a coworker. Next, approach a friend within your social network. Start small and work your way up" (Campbell & Ruane, 1999, p. 132).

FEEDBACK LOOPS IN TREATMENT: **Panic Disorder**

Invariably, medication—which changes neurological functioning—stops exerting its beneficial effect when the patient stops taking it. The positive changes in neural communication and brain activity, and the associated changes in thoughts, feelings, and behaviors do not endure. Eventually, the symptoms of panic disorder return. For some patients, though, medication is a valuable first step, providing enough relief from symptoms that they are motivated to obtain CBT, which can change their reactions (psychological factor) to perceived bodily sensations (neurological factor). When a patient receives both medication and CBT, however, the medication should be at a low enough dose that the patient can still feel the sensations that led to panic in the past (Taylor, 2000). In fact, the dose should be gradually decreased so that the patient can experience enough anxiety to be increasingly able to make use of cognitive-behavioral methods. It is the CBT that leads to enduring changes: Researchers have found that adding medication to CBT doesn't provide an advantage over CBT alone (de Beurs et al., 1999). This finding has led to CBT's being recommended even for those who prefer medication (Ellison & McCarter, 2002). Whether it involves medication or CBT or both, successful treatment will probably lead the patient, especially if he or she also has agoraphobia, to become more independent—which in turn can change the person's relationships, particularly with their safe people (social factor). These factors and their feedback loops are summarized in Figure 7.7.

Figure 7.7

7.7 ▶ Feedback Loops in Treating Panic Disorder and Agoraphobia

Earl Campbell's Anxiety

The most appropriate diagnosis for Campbell appears to be panic disorder with agoraphobia. Despite using medication, Campbell continues to have some panic symptoms, but he makes good use of various cognitive and behavioral methods and of social support. He acknowledged his continuing efforts: “Even though crowds and noise bother me, I’ll push myself to tolerate them for as long as I can. I know I must keep trying to get past the fear. It takes far more discipline for me to get through an average day with panic than it took for me to perform as a top running back in the NFL. The challenges of panic are greater” (Campbell & Ruane, 1999, p. 199).

In the rest of the chapter we examine other anxiety disorders, disorders not applicable to Campbell. As we discuss these other anxiety disorders, we consider Howard Hughes and his symptoms of anxiety, and the role these symptoms played in his life.

Key Concepts and Facts About Panic Disorder (With and Without Agoraphobia)

- The hallmark of panic disorder is recurrent panic attacks—periods of intense dread, fear, and feelings of imminent doom along with increased heart rate, shortness of breath, and other signs of hyperarousal. Panic attacks may be cued by particular stimuli (usually internal sensations), or they may arise without any clear cue. Panic disorder also involves fear of further attacks and, in some cases, restricted behavior in an effort to prevent further attacks.
- People in different cultures may have similar—but not identical—constellations of panic symptoms, such as *ataque de nervios* and wind-and-blood pressure.
- Some people with panic disorder also develop agoraphobia—avoiding situations that might trigger a panic attack or from which escape would be difficult, such as crowded locations or tunnels. Less commonly, people develop agoraphobia without panic disorder.
- Neurological factors that contribute to panic disorder and agoraphobia include:
 - A heightened sensitivity to detect breathing changes, which in turn leads to hyperventilation, panic, and a sense of needing to escape. This mechanism involves withdrawal emotions and the right frontal lobe, the amygdala, and the hypothalamus.
 - Too much norepinephrine (produced by an over-reactive locus coeruleus), which increases heart and respiration rates and other aspects of the fight-or-flight response.
 - A genetic predisposition to anxiety disorders, which makes some people vulnerable to panic disorder and agoraphobia.
- Psychological factors that contribute to panic disorder and agoraphobia include:
 - Conditioning of the initial bodily sensations of panic (interoceptive cues) or of external cues related to panic attacks, which leads them to become learned alarms and elicit panic symptoms. Some individuals then develop a fear of fear and avoid panic-related cues.
 - Heightened anxiety sensitivity and misinterpretation of bodily symptoms of arousal as symptoms of a more serious problem, such as a heart attack, which can, in turn, lead to hypervigilance for—and fear of—further sensations and cause increased arousal, creating a vicious cycle.
- Social factors related to panic disorder and agoraphobia include:
 - greater than average number of social stressors during childhood and adolescence;
 - the presence of a safe person, which can decrease catastrophic thinking and panic.
 - cultural factors, which can influence whether people develop panic disorder.
- The treatment that targets neurological factors is medication, specifically benzodiazepines for short-term relief and antidepressants for long-term use.
- CBT is the first-line treatment for panic disorder and targets psychological factors. Behavioral methods focus on the bodily signals of arousal, panic, and agoraphobic avoidance. Cognitive methods (psychoeducation and cognitive restructuring) focus on the misappraisal of bodily sensations and on mistaken inferences about them.
- Treatments that target social factors include group therapy focused on panic disorder, and couples or family therapy, particularly when a family member is a safe person.

Making a Diagnosis

- Reread Case 7.2 about S, and determine whether or not her symptoms meet the criteria for panic disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 7.3 about Shirley B., and determine whether or not her symptoms meet the criteria for agoraphobia with or without panic disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Social Phobia (Social Anxiety Disorder)

Earl Campbell and Howard Hughes were alike in that their anxiety symptoms did not significantly affect their lives until adulthood, after both men had already attained professional success. Although Howard Hughes did not appear to have experienced panic attacks, he had other anxiety-related problems. Let's examine his life and travails with anxiety.

Hughes grew up in Texas as an only child in a wealthy family; his father founded a tool company and was often traveling on business. As a child and teenager, Hughes was shy and had only one friend; he was “supersensitive”—he didn't seem to take teasing in stride as other children did—and he preferred to be alone or spend time with his mother. When he was almost 17, his mother, a homemaker, died unexpectedly of complications from a minor surgical procedure. Two years later, Hughes became an orphan: His father died unexpectedly of a heart attack. Hughes was independent and rich at the age of 19. Within the next 6 years, he'd have triumphs and disasters: He'd win an Academy Award and survive a horrific airplane crash that crushed his cheekbone. Four years later, he'd found Hughes Aircraft Company, and 3 years after that, set a world record for flight. During his lifetime, Howard Hughes was famous for these accomplishments. But after his death in 1976, he became famous for his bizarre behavior in the last decades of his life, portrayed in the films *The Aviator*, *Melvin and Howard*, and *The Amazing Howard Hughes*, among others.

As Hughes became more successful, he also became reclusive, seeing fewer and fewer people. But it wasn't simply that he became a hermit. He went through periods of time when he would do nothing but watch films, 24 hours a day, naked, moving only from bed to chair and back, with occasional forays to the bathroom. And “raised to believe in his own delicate nature and in the grave danger of being exposed to germs, he became obsessed about his health, and feared that he too was destined for an early death. The slightest change in his physical condition or the mildest illness now threw him into a panic. He began to take pills and resort to all sorts of precautions to insulate himself from disease and illness. It was an obsession that would grow with time” (Barlett & Steele, 1979, p. 52). When asked about this behavior, he defended it by saying, “Everybody carries germs around with them. I want to live longer than my parents, so I avoid germs” (Fowler, 1986).

Clearly, Hughes's behavior wasn't normal. But what was the matter with him? Where is the line drawn between normal shyness and an extreme reaction to social situations or any other feared object or situation? At what point did Hughes's concerns about health and germs become unreasonable? To answer these questions, let's explore social phobia (also called *social anxiety disorder*) and then examine other types of anxiety disorders from which Hughes may have suffered.

What Is Social Phobia?

Howard Hughes had always been quiet and shy, and he had problems relating normally to people. Even after he became famous as a film producer and aviator, he was still shy—to the point that, when dating the actress Katherine Hepburn and visiting her at her family's home, he refused to join the family for dinner and insisted on waiting to eat until everyone had left the table so that he could eat alone. His problems got worse: In his 50s and 60s, he refused to see anyone but his immediate aides, except for a few times when legal matters required him to interact face to face with a handful of other people. These behaviors are evidence of something more extensive than shyness; they are symptoms of social phobia.

Social phobia, also called *social anxiety disorder*, is an intense fear of public humiliation or embarrassment, together with the avoidance of social situations likely to cause this fear (American Psychiatric Association, 2000; see Table 7.8). Such social situations often include those where a person could be judged—for instance, public speaking. Social phobia may also arise in social situations in which

Social phobia

The anxiety disorder characterized by intense fear of public humiliation or embarrassment, together with the avoidance of social situations likely to cause this fear; also called *social anxiety disorder*.

Table 7.8 ▶ DSM-IV-TR Diagnostic Criteria for Social Phobia

<p>A. A marked and persistent fear of one or more social or performance situations in which the person is exposed to unfamiliar people or to possible scrutiny by others. The individual fears that he or she will act in a way (or show anxiety symptoms) that will be humiliating or embarrassing.</p> <p>Note: In children, there must be evidence of the capacity for age-appropriate social relationships with familiar people and the anxiety must occur in peer settings, not just in interactions with adults.</p>
<p>B. Exposure to the feared social situation almost invariably provokes anxiety, which may take the form of a situationally bound or situationally predisposed Panic Attack.</p> <p>Note: In children, the anxiety may be expressed by crying, tantrums, freezing, or shrinking from social situations with unfamiliar people.</p>
<p>C. The person recognizes that the fear is excessive or unreasonable.</p> <p>Note: In children, this feature may be absent.</p>
<p>D. The feared social or performance situations are avoided or else are endured with intense anxiety or distress.</p>
<p>E. The avoidance, anxious anticipation, or distress in the feared social or performance situation(s) interferes significantly with the person's normal routine, occupational (academic) functioning, or social activities or relationships, or there is marked distress about having the phobia.</p>
<p>F. In individuals under age 18 years, the duration is at least 6 months.</p>
<p>G. The fear or avoidance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition and is not better accounted for by another mental disorder (e.g., Panic Disorder With or Without Agoraphobia, Separation Anxiety Disorder [discussed in Chapter 14], Body Dysmorphic Disorder [Chapter 8], a Pervasive Developmental Disorder [Chapter 14], or Schizoid Personality Disorder [Chapter 13]).</p>
<p>H. If a general medical condition or another mental disorder is present, the fear in Criterion A is unrelated to it, e.g., the fear is not of Stuttering, trembling in Parkinson's disease, or exhibiting abnormal eating behavior in Anorexia Nervosa or Bulimia Nervosa [Chapter 10].</p> <p>Source: Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Text Revision, Fourth Edition, (Copyright 2000) American Psychiatric Association.</p>

most people wouldn't think twice about being judged, such as eating in the presence of others or using public restrooms or dressing rooms. People with social phobia avoid such situations whenever possible—and may even avoid making eye contact with other people. When a social situation cannot be avoided and must be endured, the person with social phobia experiences panic or anxiety, sometimes including symptoms of upset stomach, diarrhea, sweating, muscle tension, and heart palpitations. DSM-IV-TR distinguishes between a social phobia that is limited to specific social performances where the individual is the center of attention—such as making a presentation—and *generalized social phobia*, which leads a person to fear and avoid all social situations, as does Rachel in Case 7.4. Table 7.9 lists additional facts about social phobia.

CASE 7.4 ▶ FROM THE OUTSIDE: Social Phobia

Rachel was a twenty-six-year-old woman who worked as an assistant manager of a small bookstore. [She sought treatment] for her intense anxiety about her upcoming wedding. Rachel wasn't afraid of being married (i.e., the commitment, living with her spouse, etc.); she was terrified of the wedding itself. The idea of being on display in front of such a large audience was almost unthinkable. In fact, she had postponed her wedding on two previous occasions because of her performance fears. . . .

She reported being shy from the time she was very young. When she was in high school, her anxiety around people had become increasingly intense and had affected her school life. She was convinced that her classmates would find her dull or boring or that they would notice her anxiety and assume that she was incompetent. Typically, she avoided doing oral reports

continued on next page

at school and didn't take any classes where she felt her performance might be observed or judged by her classmates (e.g., gym). On a few occasions, she even went out of her way to obtain special permission to hand in a written essay instead of doing an oral report. Despite being an excellent student, she generally tended to be very quiet in class and rarely asked questions or participated in class discussions.

Throughout college, Rachel had difficulty making new friends. Although people liked her company and often invited her to parties and other social events, she rarely accepted. She had a long list of excuses to get out of socializing with other people. She was comfortable only with her family and several longtime friends but aside from those, she tended to avoid significant contact with other people.

(Antony & Swinson, 2000a, pp. 5–6)

People who have social phobia also tend to be very sensitive to criticism and rejection and to worry about not living up to the perceived expectations of others. Thus, they often dread being evaluated or taking tests, and they may not perform up to their potential at school or work. Unfortunately, their diminished performance

Table 7.9 ▶ Social Phobia Facts at a Glance

Prevalence

- Social phobia is one of the most common anxiety disorders, with prevalence estimates ranging from 3% to 13%.
- Among all psychological disorders, it is the third most common, after major depression and alcohol abuse.
- A fear of public speaking or public performance is the most common symptom, followed by a fear of talking to strangers or meeting new people.

Comorbidity

- Among those with social phobia, over half will also have one other psychological disorder at some point in their lives, and 27% will have three or more disorders during their lives (Chartier, Walker, & Stein, 2003). Approximately 20–44% will have a mood disorder (Chartier, Walker, & Stein, 2003; Roth & Fonagy, 2005), and 23% will have alcohol or substance abuse or dependence (Chartier et al., 2003).

Onset

- Most people with social phobia were shy as children, and the more intense symptoms generally appear during adolescence.

Course

- Social phobia may develop gradually, or it may begin suddenly after a humiliating or stressful social experience.
- Symptoms typically are chronic, although they may lessen for some adolescents as they enter adulthood.

Gender Differences

- Three women develop social phobia for every two men with the disorder (Kessler et al., 1994).

Cultural Differences

- Culture can influence the specific form of social phobia symptoms; for instance, in Japan, some people with social phobia may fear that their body odor will offend others (Dinnel, Kleinknecht, & Tanaka-Matsumi, 2002), whereas people with social phobia in Hong Kong are more likely to be afraid of talking to individuals who are of a higher social status (Lee et al., in press).
- The prevalence of social phobia is increasing; people born more recently are more likely to develop social phobia in their lifetimes (Heimberg et al., 2000).

Source: Unless otherwise noted, information in the table is from American Psychiatric Association, 2000.

challenges their self-esteem, increasing their anxiety during subsequent performances or tests. Similarly, achievement at work may suffer because they avoid social situations that are important for advancement on the job, such as making presentations. People with social phobia are less likely to marry or have a partner than people who do not have this disorder. People with severe social phobia may quit school and be unable to get a job because the social interactions required at school or work are more than they feel they can endure.

Sometimes, a clinician or researcher cannot easily distinguish whether an individual's symptoms indicate that he or she has a social phobia or panic disorder with agoraphobia. However, there are two key features that distinguish these disorders:

1. People with social phobia fear other people's scrutiny.
2. People with social phobia rarely have panic attacks when alone.

In contrast, people who have panic disorder with agoraphobia do not exhibit these features.

Did Howard Hughes have social phobia? Biographical material suggests that he may well have: Although we don't know the degree of his fear of certain types of social situations (Criterion A), he is reported to have avoided parties and other occasions that involved meeting large numbers of people, whenever possible. However, in the first few decades of building his empire, he met with strangers or large groups of people when it served his business ends and he did not appear to have had panic attacks in the process. As a child, Hughes tried to avoid many social situations that seemed to make him anxious, and this preference continued throughout his adulthood (Barlett & Steele, 1979) (Criterion B).

Did Hughes recognize that his fear was excessive or unreasonable (Criterion C)? For a man as wealthy and powerful as Hughes, we can't know what he considered unreasonable or excessive. This was a man who accomplished achievements that others thought impossible or ridiculous. When he could, he avoided social situations that caused him anxiety, although when business required it, he endured uncomfortable situations (Criterion D). His social fears and avoidance significantly interfered with his life in the sense that they contributed to his becoming a recluse—he was last seen in public in 1958, when he was 53 years old (“The Hughes legacy,” 1976).

These considerations lead us to infer that Hughes may have had social phobia as an adult, but this would not have been a lifelong diagnosis: For most of his adult life, the severity of his symptoms waxed and waned, and there were many periods when his symptoms do not appear to have met the criteria for this disorder.

Understanding Social Phobia

Social phobia is best understood as arising from interacting neuropsychosocial factors. Because of the very nature of this disorder, social factors are prominent contributors to it, along with neurological and psychological factors. As we'll see, Howard Hughes's history indicates that all three types of factors contributed to his problems: neurological and psychological vulnerabilities and social events that exacerbated his shyness.

Neurological Factors

Why does social phobia exist at all? Evolutionary psychologists speculate that social phobia may have its origins in behaviors of animals that are lower on a dominance hierarchy: Less powerful animals fear aggressive action from those more dominant and therefore behave submissively toward them. It is possible that social phobias arise when this innate mechanism becomes too sensitive or otherwise responds improperly (Hofmann, Moscovitch, & Heinrichs, 2002).

Various facts about the brains of people with social phobia are consistent with this conjecture. As we shall see, a variety of brain areas are overly active in these patients (including those involved in fear), neurotransmitter systems do not operate normally (particularly dopamine), and these people may even have a genetic predisposition for developing one of several disorders, including social phobia.

Brain Systems and Neural Communication

Social phobia involves fear, and researchers have shown repeatedly that the amygdala is strongly activated when animals—including humans—are afraid (Rosen & Donley, 2006). Thus, it's no surprise that the amygdala is more strongly activated when people with social phobia see faces with negative expressions (such as anger) than when they see happy faces, and that this difference is greater than observed in control participants who do not have the disorder (Phan et al., 2006). In addition, the more symptoms of social phobia a person has, the more strongly the amygdala is activated when the person views faces with negative expressions. Although it's not possible to identify cause and effect here, this correlation has the potential to provide an objective way to diagnose the severity of the disorder.

The amygdala is not the only brain area that responds differently in people with social phobia. Researchers have shown that a number of brain areas, including the hippocampus and cortical areas near it, do not function normally in people who have the disorder (Furmark et al., 2002). Moreover, the right hemisphere appears to play a part in this disorder, which is not surprising, given its role in withdrawal emotions (Davidson, 1992; see Chapter 2).

Virtually all of the major neurotransmitters may function abnormally in individuals who have social phobia, but impaired dopamine activity may be particularly important (Li, Chokka, & Tibbo, 2001). Researchers have examined regions of the brain that rely on dopamine and found that patients with social phobia show less activation in these regions than do control participants. Specifically, parts of the basal ganglia that control automatic behaviors, such as those learned when one becomes adept at playing the piano, rely on dopamine—and these areas are less activated in patients with social phobia than in control groups when participants are learning automatic behaviors (Sareen et al., 2007). But dopamine dysfunction cannot be the whole story; for example, evidence that people with social phobia have too little serotonin may suggest why SSRIs have sometimes been found to help these patients (Gorman & Kent, 1999; Lykouras, 1999).

Genetics

As is the norm for anxiety disorders, social phobia appears to arise from both genetic factors and environmental factors (Mathew, Caplan, & Groman, 2001; Stein, Jang, & Livesley, 2002). The heritability of social phobia is about 37% on average (with a range of 12–60% in various studies) (Beatty et al., 2002; Fyer, 2000; Kendler et al., 1992; Li, Chokka, & Tibbo, 2001; Neale et al., 1994). However, the genetic basis for this disorder appears not to lie in specific genes that affect only social behavior; rather, the genetic characteristics that predispose a person to develop this disorder may also predispose a person to develop autism or have fragile X syndrome (Coupland, 2001).

Given a general genetic predisposition, why would one person develop social phobia and another develop, say, autism? The answer may lie in the feedback loops among factors. Specifically, if a child is confronted with negative social events (such as those that occur in an abusive or overcontrolling family) and the social setting does not help him or her develop good ways to cope with such situations (as may occur when other family members exhibit poor ways to cope with anxiety), the child may respond by developing certain behavioral tendencies that (perhaps via reinforcement mechanisms, as discussed shortly) develop into social phobia.

Furthermore, we noted earlier that some people with social phobia were extremely shy as children; they had what is called a shy temperament, or *behavioral inhibition* (Biederman et al., 2001; Kagan, 1989), which has a genetic component. These patients cannot really be said to have *developed* a phobia, since they always had a basic level of discomfort in particular social situations (Coupland, 2001). This was certainly true of Howard Hughes, who was shy as a child and continued to be shy in his adult years; he preferred small dinner parties in people's homes to large social events.

Psychological Factors

Three types of psychological factors influence the emergence and maintenance of social phobia: cognitive biases and distortions, classical conditioning, and operant conditioning.

Cognitive Biases and Distortions

People who have social phobia have particular biases in attention and memory (Ledley & Heimberg, 2006; Lundh & Öst, 1996; Wenzel & Cochran, 2006). At the outset of one study, participants were shown photos of faces and asked to judge each facial expression as critical or accepting (Lundh & Öst, 1996). Following this, they were shown a larger set of faces and asked to pick out the ones that they had been shown initially. Those with social phobia were more likely to recognize the faces that they had earlier judged as critical, whereas those without social phobia were more likely to recognize faces that they had judged as accepting. Thus, people with social phobia seem to pay more attention to—and hence better remember—faces that they perceive as critical, which in turn feeds into their fears about being evaluated.

Similarly, cognitive distortions about the world can lead people with social phobia to see it as a very dangerous place; they then become chronically hypervigilant for potential social threats and negative evaluations by others (Beck & Emery, 1985; Joorman & Gotlib, 2006; Rapee & Heimberg, 1997). Of course, such anxious apprehension about social situations usually is not rational. People with social phobia also use distorted *emotional reasoning* as proof that they will be judged negatively: They evaluate the impression they made on others based on how anxious they became during the interaction, regardless of what actually transpired. So, for instance, a woman who is very nervous when giving a talk will base her evaluation of her performance not on how well she conveyed her message or by the response of the audience, but by how anxious she felt. People with social phobia interpret ambiguous cues as negative, which becomes proof that they were correct in their concerns. For example, people with social phobia are more likely than control participants to perceive neutral—and even happy—facial expressions as being negative (Stevens, Gerlach, & Rist, 2008). The anxious woman giving a talk may interpret the fact that some audience members in the front row are leaning forward in their seats during her talk as proof that they are “waiting for me to falter or make a jerk out of myself” rather than that they might be leaning in to hear her better or might be stretching their backs. People with social phobia also tend to have less positive beliefs about their own personality traits and social abilities compared to people who do not have this anxiety disorder (Rapee & Abbott, 2006; Wilson & Rapee, 2006). Such distorted thinking about self and social situations maintains the social phobia.

Unfortunately, such cognitive biases and distortions don’t occur only during anxiety-provoking social encounters. People with social phobia persist in evaluating their social interactions long after others stop: Compared to nonanxious control participants, when asked to give an impromptu speech, those with social phobia were more like to assess their performance negatively and to ruminate on their performance a week later (Abbott & Rapee, 2004).

Classical Conditioning

In some cases, classical conditioning can contribute to the development of social phobia: A social situation (the conditioned stimulus) becomes paired with a negative social experience (such as public humiliation) to produce a conditioned emotional response (Mineka & Zinbarg, 1995). The conditioned response (fear or anxiety) may generalize to other, or even all, types of social situations. Based on letters from Hughes’s mother to the director of the sleep-away camp he attended as a child, it seems that Hughes was teased by his campmates and took the teasing to heart. According to classical conditioning principles, it’s possible that the sight of these campmates or the sound of their voices became a conditioned stimulus and induced

in Hughes a powerful emotional response of humiliation or shame. He would then be likely to avoid similar stimuli.

Operant Conditioning

Operant conditioning principles apply to social phobia as well: Like a person with agoraphobia, a person with social phobia might avoid social situations in order to decrease the probability of an uncomfortable experience. The avoidant behavior does decrease anxiety and is thus reinforced (Mowrer, 1939). With each type of uncomfortable social situation that Hughes avoided, he learned that he could feel less anxious by staying away from those situations. And so, he avoided as many anxiety-provoking social situations as his money and power allowed.

Social Factors

Social factors that contribute to social phobia include the message some children receive from their interactions with family members—that social interactions can be a threat—and the influence of culture on people's concerns and fears about social interactions.

Parent-Child Interactions

Extreme overprotection by parents (as Hughes reportedly received from his mother) is associated with childhood anxiety (Hudson & Rapee, 2001; Wiborg & Dahl, 1997); such overprotection may lead children to cope with their anxiety through avoidance (Barrett et al., 1996). In Hughes's case, his mother was preoccupied and concerned about her son's shyness and his response to teasing, and she appears to have—perhaps inadvertently—reinforced his natural tendencies by letting him avoid social situations that made him uncomfortable (Fowler, 1986).

Culture

Different cultures emphasize different concerns about social interactions, and these concerns influence the specific nature of social phobia. For example, in certain Asian cultures, such as those of Korea and Japan, a person with social phobia may be especially afraid of offending others; in particular, he or she may fear that his or her body odor or blushing will be offensive. In Japan, this fear is known as *taijin kyofusho* (Dinnel, Kleinknecht, & Tanaka-Matsumi, 2002; Guarnaccia, 1997a). This contrasts with a fear among North Americans and Europeans of being humiliated by something they say or do (Lee & Oh, 1999).

The results from one study suggest that social phobias are becoming more common over time, and a higher proportion of people in more recent birth cohorts will develop the disorder (Heimberg et al., 2000).

FEEDBACK LOOPS IN ACTION: Understanding Social Phobia

A genetic or other neurological vulnerability, such as a shy temperament, can predispose people to developing social phobia (Bienvenu et al., 2007). The neurological vulnerability both contributes to and is affected by distorted thinking and conditioning to social situations (psychological factors). In addition, the anxiety and cognitive distortions may be triggered by a negative social event (social factor) and are then perpetuated by negative self-evaluations and avoidance of the feared social interactions (Antony & Barlow, 2002). Based on these psychological factors, people with social phobia may interact with others in ways that lead other people to rebuff them (Taylor & Alden, 2006), confirming their own negative view of themselves and of social interactions.

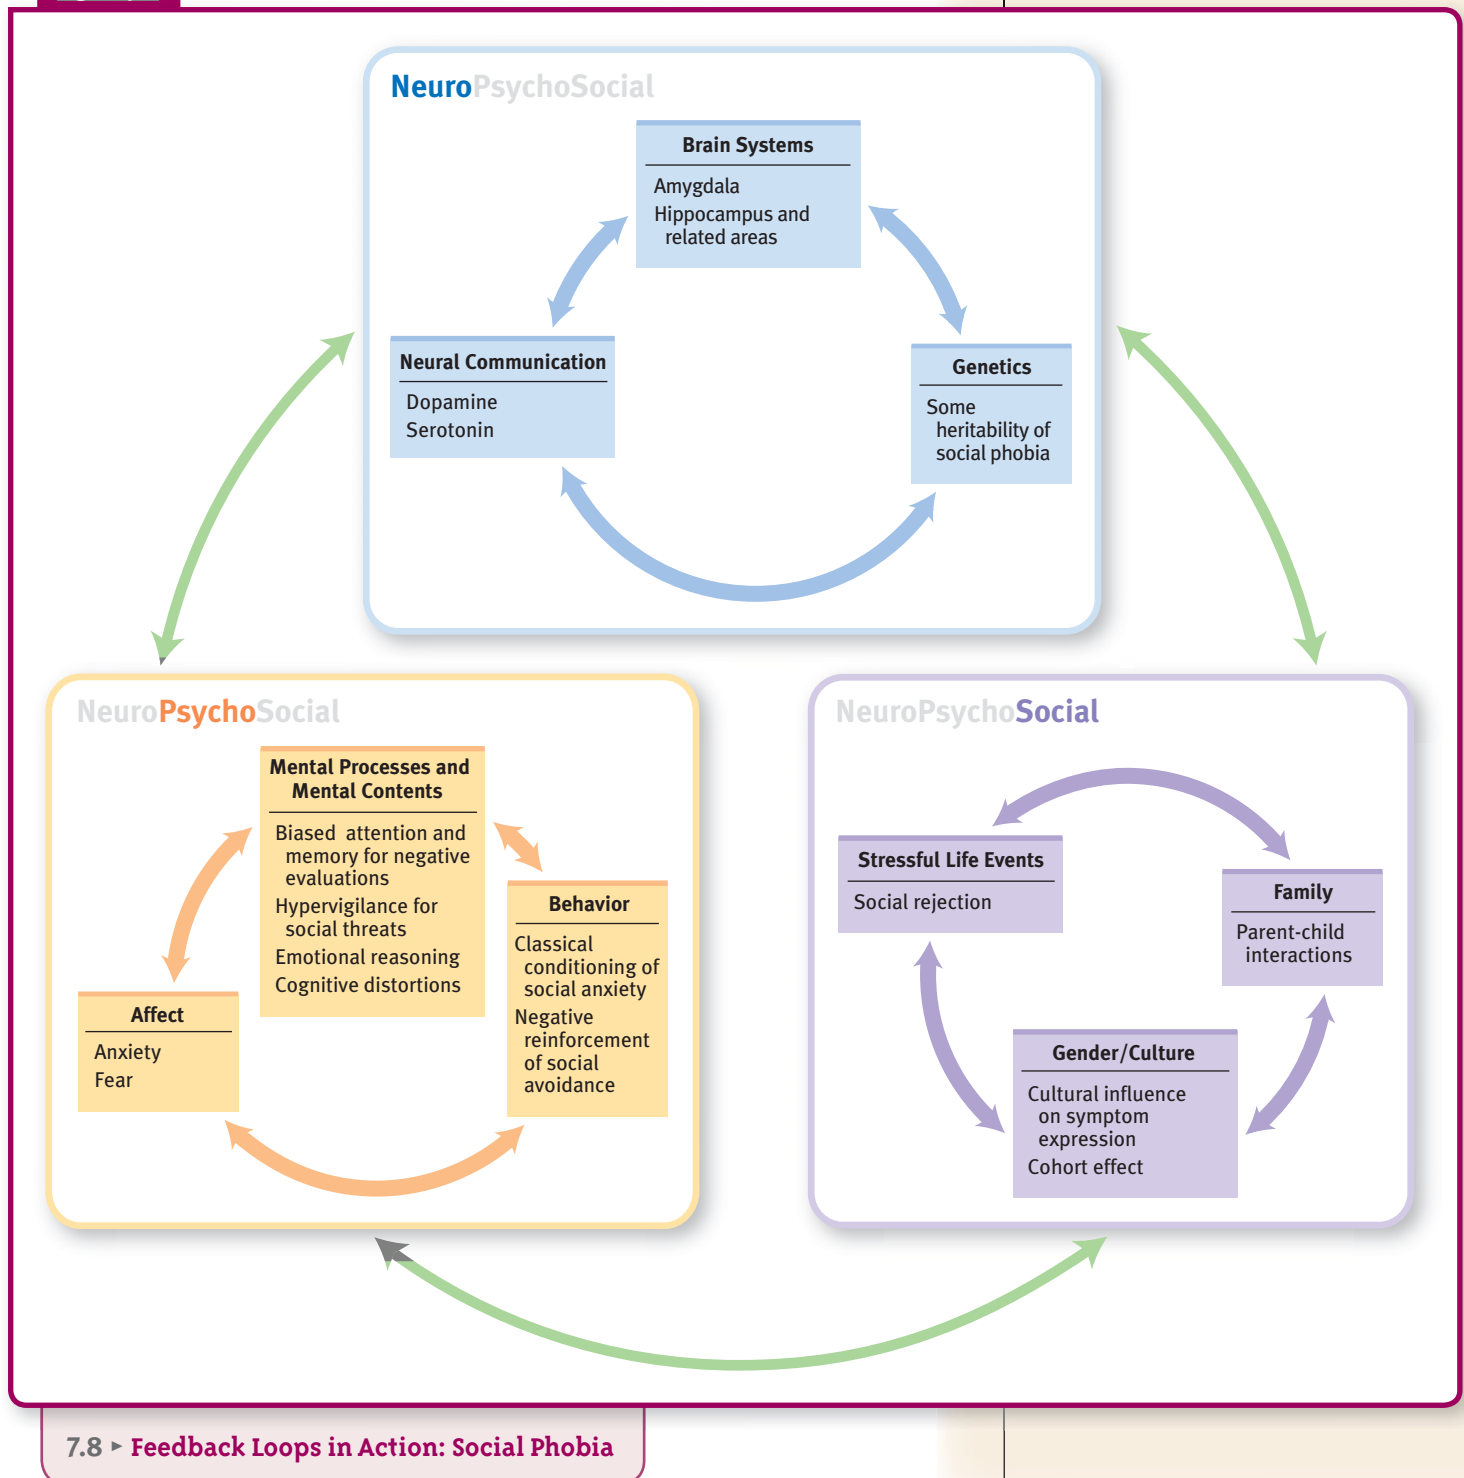

Furthermore, within the classical conditioning framework, both the unconditioned stimulus and the conditioned stimulus pertain to social interactions. Thus, the classical conditioning of social phobia is an event that involves social and psychological factors, as well as neurological ones—given that brain functioning is altered through the conditioning. Figure 7.8 illustrates these factors and their feedback loops.

Bob Daemrich/Photo Edit

Culture can influence the nature of the symptoms of social phobia. In Korea, for example, social fears called *taijin kyofusho* involve the possibility of offending others, perhaps through body odor or blushing.

Figure 7.8

Treating Social Phobia

Various forms of treatment are effective for social phobia; each one targets neurological, psychological, or social factors, but will affect the other types of factors. Ultimately, the success of any form of treatment is reflected in diminished social fears and avoidance. Unfortunately, none of the treatments described here had been sufficiently developed when Hughes's symptoms were at their apex.

Some people with social phobia dread speaking in any group situation—such as a class or a meeting—to the extent that they are willing to be evaluated negatively for remaining quiet. Exposure and cognitive methods can help diminish the anxiety and avoidance.

image00/Alamy

Targeting Neurological Factors: Medication

For people whose social fears are limited to periodic performances—whether a business presentation, a class presentation, or an onstage performance—a beta-blocker, such as *propranolol* (Inderal), is the medication of choice (Rosenbaum et al., 2005). Beta-blockers bind to some of the brain’s receptors for epinephrine and norepinephrine, and hence make these receptors less sensitive. Both of these neurotransmitters are released during the fight-or-flight response. Thus, if the person perceives a “threat” and more epinephrine or norepinephrine is released as part of the fight-or-flight response, he or she will not experience its physical effects, such as increased heart rate, after taking a beta-blocker (see Figure 7.1 for a detailed list of the physical effects of the fight-or-flight response). Beta-blockers are not sedating.

For those whose social anxiety arises in a wider and more frequent set of circumstances, the medication of choice is the SSRI *paroxetine* (Paxil) or *sertraline* (Zoloft). Other SSRIs and SNRIs, such as *venlafaxine* (Effexor) and *nefazodone* (Serzone), and NaSSAs, such as *mirtazapine* (Remeron), can also help treat social phobia (Rivas-Vazques, 2001; Van der Linden, Stein, & van Balkom, 2000). However, higher doses of these medications are necessary to treat social phobia than to treat depression, and the medications may need to be taken for at least 6 months before the patient’s fears and avoidance decrease (Rosenbaum et al., 2005). These medications affect the amygdala and the locus coeruleus, decreasing their activation. As with panic disorder, medication may be effective in treating social phobia in the short run (Federoff & Taylor, 2001), but symptoms generally return when medication is discontinued; thus, CBT is often also appropriate.

Hughes did take medication, but not specifically for his social phobia. Following a plane crash when he was about 40, he was so badly injured he wasn’t expected to live through the night. He was given morphine for the pain. He did recover, although he remained in the hospital for 2 months, during which time he received increasing doses of morphine. His doctors later switched his pain medication to codeine, a drug he continued to take in ever-increasing quantities over the rest of this life. In his 50s, he also began taking the benzodiazepine Valium. Although the codeine and Valium may have taken the edge off his social phobia, they are very addictive and certainly interfered with his cognitive functioning.

Targeting Psychological Factors: Exposure and Cognitive Restructuring

CBT is used to treat social phobia, and there is evidence that such therapy has effects on the brain that are comparable to those of some medications; both sorts of treatments actually reduce the activity in certain key brain areas. For example, one study investigated two kinds of treatments with participants who had untreated social phobia (Furmark et al., 2002). The study began by scanning the participants’ brains as they performed a public speaking task—which made them all anxious. Each participant was then randomly assigned to one of three groups: After the first scan, members of one group received the SSRI *citalopram*, members of another received CBT, and members of the third group were placed on a waiting list.

Nine weeks after the first scan, patients in the two treatment groups had improved by the same amount; however, patients in the waiting list group did not improve. At this point, all participants received a second brain scan, again while they performed the public speaking task. Comparison of the before and after brain scans revealed that a host of brain areas had less activity after treatment, particularly those involved in fear (and related emotions) and memory. Specifically, as shown in Figure 7.9, the amygdala, the hippocampus, and related areas were activated less strongly during the second scan, and the activation decreased comparably for the participants in the two treatment groups. The patients who responded best to treatment showed the greatest decrease in activation, which fits nicely

Figure 7.9**7.9 ▶ Effects of CBT and an SSRI on**

Brain Activity Results from a study by Furmark and colleagues (2002) show that activity in the amygdala, the hippocampus, and related areas was reduced by both CBT (a) and the SSRI citalopram (b). Brighter colors indicate greater reduction in activity. The scans are shown as viewed from the bottom.

Source: Furmark et al., 2002, Fig. 2-a. For more information see the Permissions section.

with other research results (Van der Linden et al., 2000). And perhaps most striking, 1 year later, the people who had the greatest reduction in activation from the first scan to the second scan were the most improved clinically. This means that the brain scans indicated how well the treatment worked for people with social phobia.

As shown by the study by Furmark and colleagues (2002), described above, cognitive methods can alleviate symptoms of social phobia. Such treatment helps individuals to identify irrational thoughts about social situations, develop more realistic thoughts and expectations, and test predictions about the consequences of engaging in specific behaviors (Antony & Barlow, 2002; Clark et al., 2006). For instance, let's say that a marketing manager is concerned that his voice might crack while making a presentation. Cognitive restructuring would address this concern: What would happen if his voice *did* crack? How could he resume his presentation? As the marketing manager identifies his automatic negative thoughts, he can develop more rational thoughts about giving presentations and develop possible solutions should his fears become reality.

In addition, the behavioral method of exposure can be very effective in treating people with social phobia: When people put themselves in social situations in order to habituate to their anxiety symptoms, their anxiety diminishes (Taylor, 1996). However, for those who do not want to participate in group therapy, or for those whose social anxiety is extremely high, exposure in individual sessions may allow them to habituate to less overwhelming stimuli that lead them to feel anxious. Following this, they are habituated to increasingly challenging stimuli. Table 4.3 (p. 127) provides an example of the kind of hierarchy of fear and avoidance of social situations that is used for exposure.

Targeting Social Factors: Group Interactions

Changing someone's thoughts and feelings about social interactions is an important part of treating social phobia (McEvoy et al., in press). However if the patient does not actually interact more with others after the treatment, then it cannot be considered a success. A patient might feel less anxious about social interactions but still avoid them out of habit. Because the very nature of the anxiety symptoms relate to social interactions, group therapy is the preferred mode of exposure treatment. Such therapy immerses people in the very type of experience that is associated with anxiety. *Cognitive-behavioral group therapy* uses exposure and cognitive restructuring in a group setting. This setting allows patients to try out their new skills immediately (Heimberg et al., 1990; Heimberg et al., 1998). Moreover, the exposure involved in group therapy helps to extinguish the conditioned bodily arousal (learned alarm) that arises in social situations. Cognitive-behavioral group therapy is as effective as medication (Davidson et al., 2004) and has the added benefit that the positive effects continue after treatment ends (Mörtberg et al., 2006).

In addition to therapy groups, there are self-help organizations for people who are afraid of speaking in public, such as Toastmasters, which give individuals an

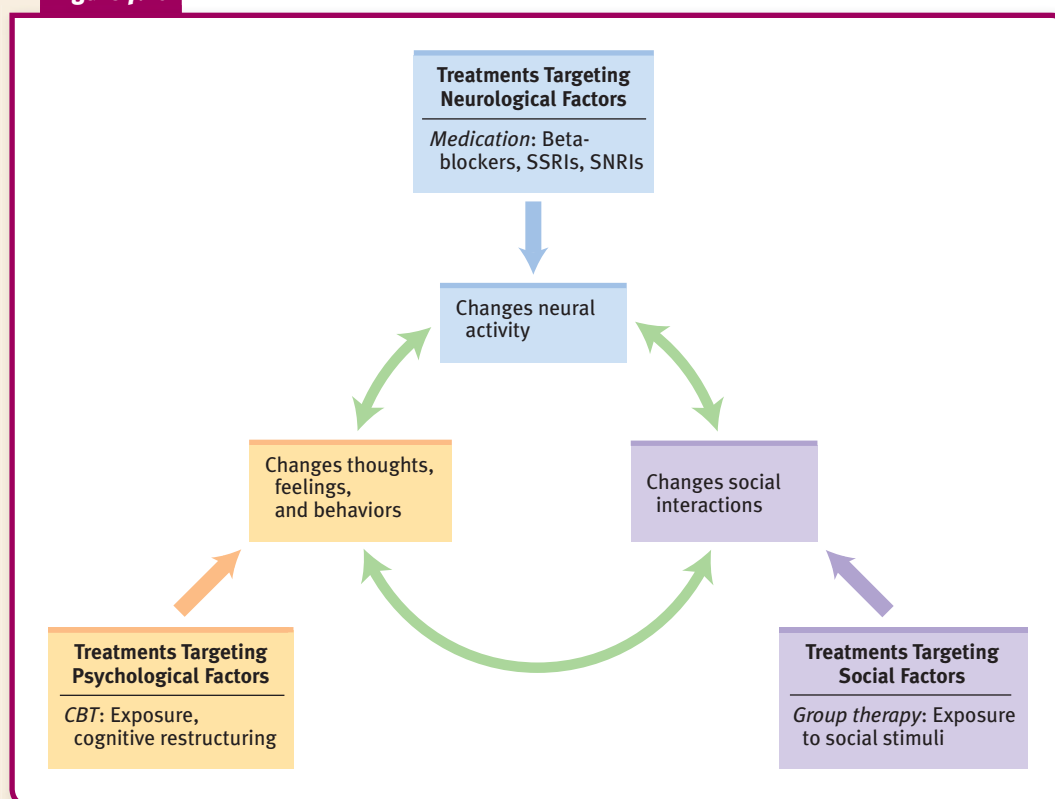

opportunity to practice making both spontaneous speeches and planned ones. (For more information, go to www.toastmasters.org.)

FEEDBACK LOOPS IN TREATMENT: Social Phobia

When medication is discontinued, symptoms of social phobia often recur. Such relapse is less likely after CBT. From a neuropsychosocial approach, CBT changes the way a patient thinks about and behaves in social situations (psychological factors). Viewing these situations more realistically and with less anxiety means that the patient does not get as physically aroused (neurological factor). This lowered arousal, along with positive or neutral expectations about the previously feared social situations, leads the patient to enter more willingly into a social situation (social factor), with less negative expectations. When such social experiences are positive, the patient feels increasing mastery (psychological factor) and less arousal (neurological factor), and perhaps receives reinforcement from others (social factor) for these changes. Figure 7.10 illustrates these factors and their feedback loops.

Figure 7.10

7.10 ► Feedback Loops in Treating Social Phobia

Key Concepts and Facts About Social Phobia (Social Anxiety Disorder)

- Social phobia is an intense fear of public humiliation or embarrassment, together with an avoidance of social situations likely to cause this fear. When such social situations cannot be avoided, they trigger panic or anxiety. Social phobia may be limited to specific types of performance-related situations or may be generalized to most social situations.
- The anxiety about performing poorly and being evaluated by others can, in turn, impair an individual's performance, creating a vicious cycle. The symptoms of social phobia may lead individuals with this disorder to be less successful than they could otherwise be, because they avoid job-related social interactions that are required for advancement.

- Neurological factors that give rise to social phobia include an amygdala that is more easily activated in response to social stimuli, too little dopamine in the basal ganglia, too little serotonin, and a genetic predisposition toward a shy temperament (behavioral inhibition).
- Psychological factors that give rise to social phobia include cognitive distortions and hypervigilance for social threats—particularly about being (negatively) evaluated. Classical conditioning of a fear response in social situations may contribute to social phobia; avoiding feared social situations is then negatively reinforced (operant conditioning).
- Social factors that give rise to social phobia include parents’ modeling or encouraging a child to avoid anxiety-inducing social interactions. Moreover, people in different cultures may express their social fears somewhat differently (e.g., *taijin kyofusho*). The rate of social phobia appears to be increasing in more recent birth cohorts.
- Medication is the treatment that targets neurological factors, specifically, beta-blockers for periodic performance anxiety, and SSRIs or SNRIs for more generalized social phobia. The treatment that targets psychological factors is CBT, specifically, exposure and cognitive restructuring. Treatments that target social factors include group CBT and exposure to feared social stimuli.

Making a Diagnosis

- Reread Case 7.4 about Rachel, and determine whether or not her symptoms meet the criteria for social phobia. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Specific Phobias

During Hughes’s convalescence after a near fatal plane crash at the age of 40, he grew concerned that he’d become afraid of flying. Before the crash, Hughes had loved to fly. But he knew that a number of his relatives had developed some extreme fears. For instance, his mother “had an intense fear of animals and was known to faint when one came near” (Barlett & Steele, 1979, p. 30). Hughes’s paternal grandmother “had developed a phobia about bugs, refusing to allow closets to be built in her new home for fear insects would nest in them” (Barlett & Steele, 1979, p. 45).

His mother also was extremely anxious about Hughes’s health—she “watched for the slightest change in his physical condition. If she detected any abnormality in his feet, teeth, digestion, or bowels, she whisked him off to a doctor for an examination. During outbreaks of infectious diseases, the two of them often left Houston for some distant, uncontaminated place” (Barlett & Steele, 1979, p. 38). Hughes himself was afraid that he’d develop an illness: “Raised to believe in his own delicate nature and in the grave danger of being exposed to germs, he became obsessed about his health. . . . He began to take pills and resort to all sorts of precautions to insulate himself from disease and illness” (Barlett & Steele, 1979, p. 52). Mental health clinicians would probably consider Hughes’s mother and grandmother—and likely Hughes himself—each to have had a *specific phobia*.

What Is Specific Phobia?

What distinguishes normal fear and avoidance of an object or situation from its “abnormal” counterpart? DSM-IV-TR describes the central element of a **specific phobia** as an excessive or unreasonable anxiety or fear related to a specific situation or object (American Psychiatric Association, 2000). People with a specific phobia know that their fear is excessive or unreasonable (see Table 7.10). (In contrast, a rational fear of being mugged in a large city park late at night and avoiding parks after dark would not be considered to be a specific phobia.) A person with a specific phobia works hard to avoid the feared stimulus, often significantly restricting his or her activity in the process (see Case 7.5). A person with an elevator phobia, for example, will choose to walk up many flights of stairs rather than take the elevator. Specific phobias you might recognize include claustrophobia (fear of small spaces), arachnophobia (spiders), and acrophobia (heights). DSM-IV-TR lists five types or categories of specific phobias: *animal*, *natural environment*, *blood-injection-injury*, *situational*, and “*other*” (American Psychiatric Association, 2000).

Specific phobia

The anxiety disorder characterized by excessive or unreasonable anxiety or fear related to a specific situation or object.

Table 7.10 ▶ DSM-IV-TR Diagnostic Criteria for Specific Phobia

- A.** Marked and persistent fear that is excessive or unreasonable, cued by the presence or anticipation of a specific object or situation (e.g., flying, heights, animals, receiving an injection, seeing blood).
- B.** Exposure to the phobic stimulus almost invariably provokes an immediate anxiety response, which may take the form of a situationally bound or situationally predisposed Panic Attack.
Note: In children, the anxiety may be expressed by crying, tantrums, freezing, or clinging.
- C.** The person recognizes that the fear is excessive or unreasonable.
Note: In children, this feature may be absent.
- D.** The phobic situation(s) is avoided or else is endured with intense anxiety or distress.
- E.** The avoidance, anxious anticipation, or distress in the feared situation(s) interferes significantly with the person's normal routine, occupational (or academic) functioning, or social activities or relationships, or there is marked distress about having the phobia.
- F.** In individuals under age 18 years, the duration is at least 6 months.
- G.** The anxiety, Panic Attacks, or phobic avoidance associated with the specific object or situation are not better accounted for by another mental disorder, such as Obsessive-Compulsive Disorder (e.g., fear of dirt in someone with an obsession about contamination [discussed later in this chapter]), Posttraumatic Stress Disorder (e.g., avoidance of stimuli associated with a severe stressor [discussed later in this chapter]), Separation Anxiety Disorder (e.g., avoidance of school [Chapter 14]), Social Phobia (e.g., avoidance of social situations because of fear of embarrassment), Panic Disorder with Agoraphobia, or Agoraphobia Without History of Panic Disorder.

CASE 7.5 ▶ FROM THE OUTSIDE: A Specific Phobia (Hydrophobia)

Kevin described an experience in which he almost drowned when he was 11. He and his parents were swimming in the Gulf of Mexico, in a place where there were underwater canyons with currents that would often pull a swimmer out to sea. He remembered the experience very distinctly. He was standing in water up to his neck, trying to see where his parents were. Suddenly, a large wave hit him and dragged him into one of the underwater canyons. Fortunately, someone on shore saw what had happened and rescued him. After the experience, he became very much afraid of the ocean, and the fear generalized to lakes, rivers, and large swimming pools. He avoided them all.

(McMullin, 1986, p. 165)

Animal Type

The *animal type* of specific phobia pertains to an extreme fear or avoidance of any variety of animal; commonly feared animals include snakes and spiders. Symptoms of the animal type of specific phobia usually emerge in childhood. People with a phobia for one kind of animal often also have a phobia for another kind of animal. Hughes's grandmother and mother had this type of phobia, although his mother's fainting in response to seeing an animal is unusual.

Natural Environment Type

The *natural environment* type of specific phobia typically focuses on heights, water, or storms. Kevin, in Case 7.5, had a fear of water. Phobias about the natural environment typically emerge during childhood.

Blood-Injection-Injury Type

The *blood-injection-injury type* of specific phobia produces a strong response to seeing blood, having injections, sustaining bodily injuries, or watching surgery. This type of phobia runs in families and emerges in early childhood. A unique response of this specific phobia involves first an increased arousal, then a rapid decrease in heart

rate and blood pressure, which often causes fainting. Among people with this type of phobia, over half report having fainted in response to a feared stimulus (Öst, 1992).

Situational Type

A *situational type* of specific phobia involves a fear of a particular situation, such as being in an airplane, elevator, or enclosed space, or of driving a car. Some people develop this type of phobia in childhood, but in general it has a later onset, often in the mid-20s. People with this type tend to experience more panic attacks than do people with other types of specific phobia (Lipsitz et al., 2002). Situational phobia has a gender ratio, age of onset, and family history similar to those of panic disorder with agoraphobia.

Some researchers have argued that situational and natural environment fears overlap; for instance, fear of the dark is both a situational and a natural environment phobia. These researchers propose that these two types should be combined or that there should be no types, and mental health professionals should simply name the feared stimuli specifically (Antony & Swinson, 2000b).

Other Type

This category includes any *other type* of specific phobia that does not fall into the four categories already discussed. Examples of specific phobias that would be classified as “other” are a fear of falling down when not near a wall or some other type of support, a fear of costumed characters (such as clowns at a circus), and a phobic avoidance of situations that may lead to choking, vomiting, or contracting an illness—the last of which Hughes may have had.

Specifics About Specific Phobias

As noted in Table 7.11, the majority of people who have one sort of specific phobia are likely to have at least one more (Stinson et al., 2007). This high comorbidity among specific phobias has led some researchers to suggest that, like social phobia, specific phobia may take two forms: a focused type that is limited to a specific stimulus, and a more generalized type that involves fear of various stimuli (Stinson et al., 2007).

The unrealistic fears and extreme anxiety of a specific phobia occur in the presence of the feared stimulus but may even occur when simply thinking about it. Often, people with a specific phobia fear that something bad will happen as a result of contact with the stimulus: “What if I get stuck in the tunnel and it cracks open and floods?” “What if the spider bites me and I get a deadly disease?” People may also be afraid of the consequences of their reaction to the phobic stimulus, such as losing control of themselves or not being able to get help: “What if I mess my pants after the spider bites me?” or “What if I faint or have a heart attack while I’m in the tunnel?” In this sense, the fear of somehow losing control is similar to that in panic disorder (Horwath et al., 1993). The situation or object that causes fear and anxiety is related to the content of the worry about losing control: Someone who is afraid of heights may worry about getting dizzy when high up (and, as a result, plummeting to the ground).

There is a very long list of stimuli to which people have developed phobias (see www.phobialist.com), but people do not seem to develop specific phobias toward all kinds of stimuli. Humans, like other animals, have a natural readiness for certain stimuli to produce certain conditioned responses. This *preparedness* means that less learning from experience is needed to produce the conditioning (Öhman et al., 1976). Young children, for example, typically go through a period when they are easily afraid of the dark or of storms, which may suggest that such fears can more readily become specific phobias. In contrast, a fear of flowers is extremely unusual. Some psychologists (Menzies & Parker, 2001; Öhman, 1986; Stein & Matsunaga, 2006) propose that such preparedness has an evolutionary advantage—people are more readily afraid of objects or situations that could lead to death, such as being too close to the edge of a cliff (and falling off) or being bitten by a poisonous snake or spider. According to this view, those among our early ancestors who were afraid of these stimuli and avoided them were more likely to survive and reproduce—and thus pass on genes that led them to be prepared to fear these stimuli.

Table 7.11 ▶ Specific Phobia Facts at a Glance

Prevalence

- Approximately 10% of Americans will experience in their lifetime a fear severe enough to meet the criteria for specific phobia (Stinson et al., 2007).

Comorbidity

- Only a quarter of those with a diagnosis of specific phobia have a single specific phobia; 50% have three or more phobias. In addition, the more phobias a person has, the more likely he or she is to have another type of anxiety disorder (Curtis et al., 1998; Stinson et al., 2007).

Onset

- There are different ages of onset for the various types of specific phobias, although the average age is about 10 years (Stinson et al., 2007).
- Specific phobias that arise after trauma can occur at any age.

Course

- Specific phobias that arise during adolescence are likely to persist through adulthood; only 20% of persistent phobias that begin in adolescence will improve without treatment.

Gender Differences

- Twice as many women are diagnosed with specific phobias as men, although this ratio varies across type of specific phobias (Stinson et al., 2007). The gender difference in prevalence rates is more pronounced with animal, natural environment, and situational phobias. Men and women are equally likely to report blood-injection-injury phobia (Fredrikson et al., 1996).
- Gender differences may reflect a reporting bias: Women may be more likely to report symptoms, but not necessarily more likely to have them (Hartung & Widiger, 1998).

Cultural Differences

- The prevalence rates of the various types of specific phobias vary across countries, suggesting that cultural factors, such as the likelihood of coming into contact with various stimuli, affect the form that specific phobias take (Chambers, Yeragani, & Keshavan, 1986).

Source: Unless otherwise noted, information in the table is from American Psychiatric Association, 2000.

Although many people fear some kind of animal, such as spiders or snakes, the fear and avoidance of that type of animal do not constitute a specific phobia unless they significantly interfere with normal functioning.

People also can have a natural disinclination to allow some particular conditioned stimuli to elicit certain conditioned responses, which is called *contrapreparedness*. For example, Marks (1969) describes a 43-year-old patient who, at the age of 10, saw a snake in a ditch just as a car door was accidentally slammed on her hand. Thirty years later, she still felt extremely afraid of snakes (preparedness), but she had no fear of car doors (contrapreparedness), despite a car door's having been the actual source of her pain.

Although Howard Hughes was worried about developing a fear of flying (specific phobia, situational type), the phobia didn't materialize. Because of his concern about becoming afraid of flying and the passion he had had for the activity, he pushed himself to get back in the cockpit as soon as he was physically able (Barlett & Steele, 1979), and then he flew repeatedly, successfully undergoing a self-imposed exposure treatment. However, Hughes may well have had a phobia of contracting an illness—his concerns were excessive and unreasonable, and his avoidance behaviors extreme.

Understanding Specific Phobias

Let's consider neurological, psychological, and social factors that contribute to specific phobias, as well as their feedback loops. For this disorder, neurological and psychological factors appear to weigh more heavily than social factors.

Neurological Factors

Researchers are making good headway in understanding the brain systems that underlie specific phobias, and there is evidence that an unusually reactive amygdala may predispose some people to develop these disorders. In addition, abnormal functioning of several neurotransmitters has been shown to contribute to specific phobias. Finally, researchers have provided solid evidence that genes play a role in specific phobias, and have also documented the role of environmental factors in triggering these genetic predispositions.

Brain Systems

Perhaps not surprisingly, our old friend the amygdala is again implicated in an anxiety disorder. In fact, the amygdala appears to have a hair-trigger in patients with specific phobia. For example, in one fMRI study, patients who were phobic of spiders and control participants were asked to match geometric figures. In this study, the trick was that in the background behind each figure—which was completely irrelevant to the task of matching the figures—was a picture of either a spider or a mushroom (because no one in the study was afraid of mushrooms). Even in this task, where the participants were not paying attention to the background pictures, the amygdala of the patients with the phobia was more strongly activated in response to the spiders than the mushrooms; this was not true for the control participants (Straube, Mentzel, & Miltner, 2006).

But the amygdala is not the only brain structure associated with the disorder. For example, in one PET study, people who had phobias of animals were shown pictures of those animals (e.g., snakes) while their brains were scanned (Rauch et al., 1995). The photos of animals not only activated various parts of the limbic system (including the amygdala), but also activated the part of the cortex (known as *somatosensory cortex*) that registers sensations on the body. One interpretation of this finding is that the pictures triggered mental imagery of bodily sensations (such as the feeling of a bug crawling on the skin); in fact, when interviewed afterward, all participants reported having both tactile sensations and visual imagery during the study.

Neural Communication

The sort of anxiety evoked by specific phobias is associated with too little of the inhibitory neurotransmitter substance GABA (File, Gonzalez, & Gallant, 1999). When a benzodiazepine (such as *diazepam*, or Valium) binds to the appropriate receptors, it facilitates the functioning of GABA. The drug thereby ultimately produces a calming effect.

In addition, lower levels of the neurotransmitter acetylcholine are associated with higher levels of anxiety (Degroot & Treit, 2002). Moreover, the systems that produce acetylcholine and serotonin appear to be linked, so that increases in the output of one are accompanied by decreases in the output of the other (File, Kenny, & Cheeta, 2000); thus, reducing the serotonin level raises the level of acetylcholine, which in turn decreases anxiety. This may be one reason why SSRIs, which lower the levels of serotonin, effectively treat anxiety disorders. Moreover, to make the situation even more complicated, norepinephrine is also implicated in anxiety. Clearly, anxiety does not result from a simple biochemical imbalance, and effective medications will need to target several different neurotransmitter substances.

Genetics

Researchers have discovered that some genes predispose individuals to develop a specific phobia (but not a particular one), whereas other genes underlie each specific type of phobia (Kendler et al., 2001; Lichtenstein & Annas, 2000). According to one theory, genetic differences may cause parts of the brain related to fear (in particular, the amygdala) to be too reactive to specific stimuli; that is, the amygdala is “prepared” to overreact to a specific stimulus, which leads to a specific phobia of that stimulus. Some people’s brains may be more prepared than others’, and so they are more likely to develop a specific phobia (LeDoux, 1996).

However, such a neural predisposition cannot be all there is to it: If it were, then when one identical twin has a specific phobia, so would the other twin, which is not always the case. As we’ve noted before, the genes predispose, but rarely determine. Rather, certain environmental events are necessary to trigger the disorder. Some theorists have hypothesized that brain damage, such as can occur in an auto accident if someone isn’t wearing a seatbelt and suffers a head injury, may be one such triggering event. And, in fact, both specific phobia and panic disorder are more likely to develop if a person has had traumatic brain injury. In one study, researchers found that 30 years after a brain injury, over 8% of the people injured had a specific phobia (Koponen et al., 2002).

However, genes do not have equal effects for all specific phobias: The different specific phobias appear to be influenced to different degrees by genetics and the environment (see Figure 7.11 for the heritabilities of types of specific phobias). Family environment also has proven to be an important risk factor for specific phobias (Kendler et al., 2001).

Can genes shed light on the sex differences for specific phobias? Perhaps to a limited degree. Men and women have comparable genetic risk for animal phobia but may have different risks for agoraphobia, situational phobias, and blood-injection-injury phobia because different genes may underlie these disorders in the two sexes (Kendler et al., 2002). However, over the long run, genetics may only moderately influence whether a person will develop a specific phobia. Unique experiences (such as falling out of a tree and then becoming afraid of heights) appear to be very important (Kendler, Karkowski, & Prescott, 1999). In fact, animal and situational phobias are most likely to arise as a consequence of specific unique experiences with that particular animal or situation.

The sum of the research findings about neurological factors suggests that particular life experiences can lead to a particular specific phobia for people who—through genes or other life experiences—are neurologically vulnerable (Antony & Barlow, 2002; see *Feedback Loops in Action* section, below).

Psychological Factors

Life experiences always have their impact via how a person perceives and interprets them. Thus, psychological factors play a key role in whether a person will develop a specific phobia. Three primary psychological factors contribute to a specific phobia: a tendency to overestimate the probability of a negative event’s occurring based on contact with the feared stimuli, classical conditioning, and operant conditioning.

Faulty Estimations

As we saw with social phobia, people who have a specific phobia have a particular cognitive bias—they believe strongly that something bad will happen when they

Figure 7.11

7.11 ► Heritabilities of Specific Phobias

Source: American Psychiatric Association, 2000.

encounter the feared stimulus (Tomarken, Mineka, & Cook, 1989). They also overestimate the probability that an unpleasant event, such as falling from a high place or an airplane's crashing into a tall building, will occur (Pauli, Wiedemann, & Montoya, 1998). People who have a specific phobia may also have perceptual distortions related to their feared stimulus. For example, a person with a spider phobia may perceive that a spider is moving straight toward him or her when it isn't (Riskind, Moore, & Bowley, 1995).

Conditioning: Classical and Operant

From a learning perspective, classical conditioning and operant conditioning could account for the development and maintenance of a specific phobia. Watson and Rayner's conditioning of Little Albert's fear of rats was the first experimental induction of a classically conditioned phobia (see Chapter 2). For Kevin, in Case 7.5, the ocean was the conditioned stimulus, the unconditioned stimulus was almost drowning, and the conditioned response was fear. Avoidance of the feared stimulus is negatively reinforced (Mowrer, 1939): The feared stimulus causes anxiety, which is then relieved by avoiding the stimulus. In Kevin's case, anxiety about water is reduced when he avoids water.

Some recent research, however, has questioned the importance of classical conditioning in the development of specific phobias. In studies of people with phobias of water, heights, and spiders, researchers usually have not found evidence that classical conditioning played the role that had been predicted (Jones & Menzies, 1995; Menzies & Clarke, 1993a, 1993b, 1995a, 1995b; Poulton et al., 1999). Further evidence for a limited role of classical conditioning comes from everyday observations: Many people experience the pairing of conditioned and unconditioned stimuli but do not become phobic.

Regardless of the extent of the role of classical conditioning, operant conditioning clearly plays a key role in maintaining a specific phobia: By avoiding the feared stimulus, a person can decrease the fear and anxiety that he or she would experience in the presence of it, which reinforces the avoidance. Hughes knew from experience with his social anxiety how easily such avoidance could narrow his life; his passion for flying motivated him to return to the skies after a disastrous plane crash.

Social Factors: Modeling and Culture

Sometimes, simply seeing other people exhibit fear of a particular stimulus is enough to make the observer become afraid of that stimulus (Mineka, Cook, & Miller, 1984). For example, if as a young child, you saw your older cousin become agitated and anxious when a dog approached, you might well learn to do the same. Similarly, repeated warnings about the dangers of a stimulus can increase the risk of developing a specific phobia of that stimulus (Antony & Barlow, 2002). After hearing about a plane crash on the news, it is no surprise that some people became afraid to fly—even though they had not been in a plane accident themselves.

Modeling is not the only way that culture can exert an effect on the content of specific phobias. Consider the fact that people in India are twice as likely as people in England to have phobias of animals, darkness, and bad weather, but are only half as likely to have social phobia or agoraphobia (Chambers, Yeragani, & Keshavan, 1986). One explanation for this finding is that women in India are apt to spend more time at home than their English counterparts, so they have less opportunity to encounter feared social situations. Similarly, dangerous and predatory animals are more likely to roam free in India than in England.

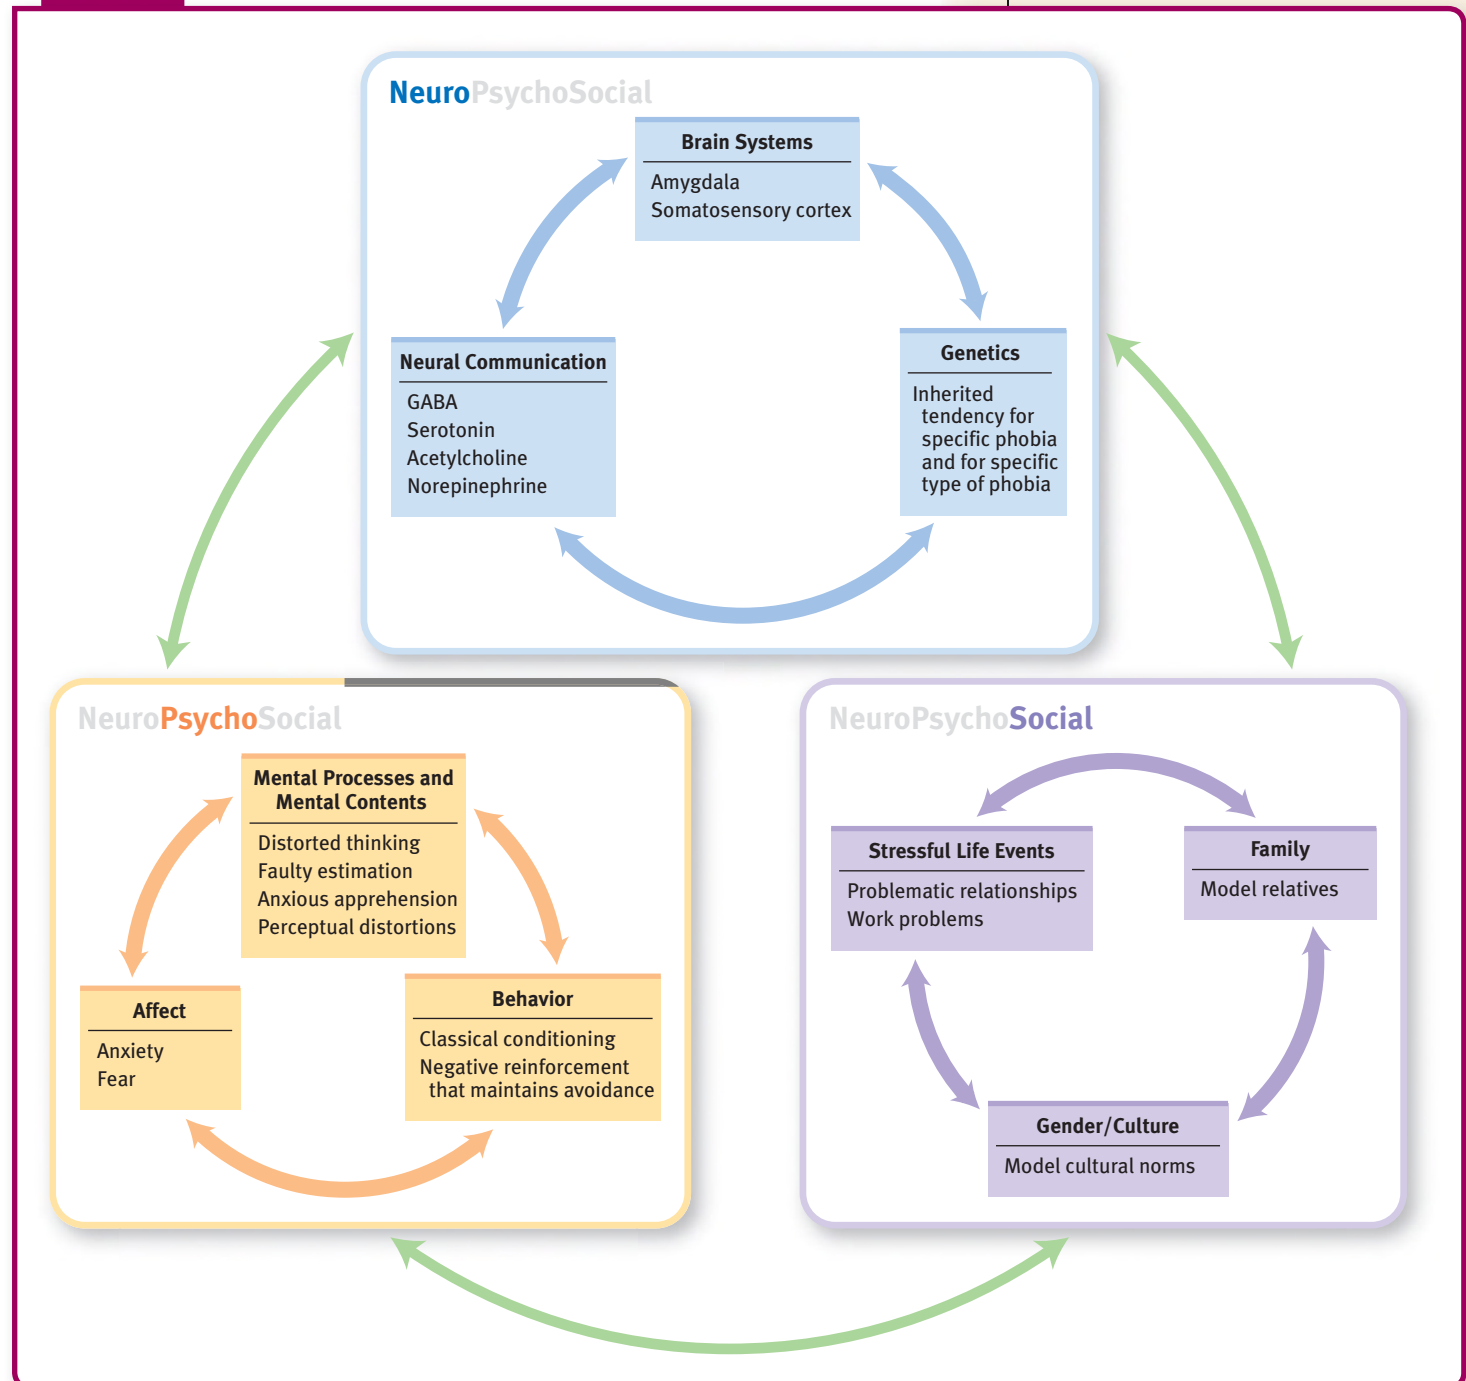

FEEDBACK LOOPS IN ACTION: Understanding Specific Phobias

A person may be neurologically vulnerable to developing a specific phobia (neurological factor), in part because of his or her genes. Through observing others' fear of a specific stimulus (social factor), the individual can become afraid and develop faulty cognitions, which can lead to anxious apprehension, distorted thinking, and the conditioning of false alarms to the feared stimulus (all psychological factors).

Given the neurological vulnerability, this set of events sets the stage for subsequent false alarms and anxious apprehension when the person is confronted with the stimulus (Antony & Barlow, 2002). And, of course, once the person begins to avoid the stimulus, the avoidance behavior is negatively reinforced. This behavior in turn affects not only the individual's beliefs but also his or her social interactions (social factors). These factors and feedback loops are illustrated in Figure 7.12.

Figure 7.12

7.12 ► Feedback Loops in Action: Specific Phobia

Treating Specific Phobias

Treatment for specific phobias generally targets one type of factor, although the beneficial changes affect all the factors. Neurological or psychological factors are usually the primary target of treatments.

Targeting Neurological Factors: Medication

Medication, such as a benzodiazepine, may be prescribed for a specific phobia (alone or in combination with CBT), but this is generally not recommended. Medication is usually unnecessary because CBT treatment—even a single session—is highly effective in treating a specific phobia (Ellison & McCarter, 2002; Öst, Ferebee, & Furmark, 1997). However, preliminary research suggests that one medication (*D-cycloserine*, an antibiotic used to treat tuberculosis) may facilitate the neural basis of fear extinction; the combination of *D-cycloserine* and exposure is more effective than exposure alone (Norberg, Krystal, & Tolin, 2008; Ressler et al., 2004).

Targeting Psychological Factors

If you had to choose an anxiety disorder to have, specific phobia probably should be your choice. This is the anxiety disorder most treatable by CBT, with up to 90% lasting improvement rates even after only one session (Gitin, Herbert, & Schmidt, 1996; Öst, Salkovskis & Hellström, 1991).

Behavioral Method: Exposure

The behavioral method of *graded exposure* has proven effective in treating specific phobias (Vansteenwegen et al., 2007), and is considered a first-line treatment. With this method, the patient and therapist progress through an individualized hierarchy of anxiety-producing stimuli or events as fast as the patient can tolerate, as in exposure treatment for social anxiety (discussed earlier in the chapter and in Chapter 4; see Table 4.3), but in this case substituting the specific feared stimulus for the feared social situation or interaction. Moreover, recent research on treating phobias with exposure suggests that virtual reality exposure works as well, at least for certain phobias (Pull, 2005), such as of flying and heights (Coelho et al., in press; Emmelkamp et al., 2001, 2002; Rothbaum et al., 2001, 2002), and this technique is part of many treatment programs for fear of flying. Howard Hughes provided himself with in vivo exposure treatment by flying very often as soon as he was well enough after the plane crash.

Exposure clearly alters not only behavior but also neural activity. Consider the results from a neuroimaging study of the effects of treating people with a spider phobia (Paquette et al., 2003): Before treatment, part of the parahippocampal gyrus and frontal cortex showed significant activity when the participants saw pictures of spiders. These brain areas were relatively quiet in those who did not have a spider phobia. When viewing pictures of spiders after successful exposure treatment, the brain activation patterns of the people with a spider phobia were similar to those of people without the phobia. Thus, the behavioral treatment led to neurological changes. Similar results were obtained in another study (Johanson et al., 2006).

For the blood-injection-injury type of specific phobia, the treatment of choice is *applied tension* (Antony & Swinson, 2000b): To prevent changes in blood pressure and fainting before exposure to the feared (and faint-inducing) stimulus, the patient tenses all bodily muscles, which increases blood pressure, thereby preventing fainting. The applied tension is followed by exposure to the feared stimulus (Öst, Fellenius, & Sterner, 1991).

Cognitive Methods

Cognitive methods for treating a specific phobia are similar to those used to treat other anxiety disorders, such as panic disorder and social phobia. The therapist and patient identify illogical thoughts pertaining to the feared stimulus, and

the therapist helps highlight discrepant information and challenges the patient to see the irrationality of his or her thoughts and expectations. Table 7.12 provides an example of thoughts that someone with claustrophobia—a fear of enclosed spaces—might have.

Group CBT may be appropriate for some kinds of phobias, such as fear of flying or of spiders (Götestam, 2002; Rothbaum et al., 2006; Van Gerwen, Spinhoven, & Van Dyck, 2006). However, unlike group CBT for social phobia, group treatment for specific phobia does not directly *target* social factors; rather, group CBT is a cost-effective way to teach patients behavioral and cognitive methods to overcome their fears.

Targeting Social Factors: A Limited Role for Observational Learning

Observational learning may play a role in the development of a specific phobia, but to many researchers' surprise, seeing others model how to interact normally with the feared stimulus generally is not an effective treatment for specific phobias. Perhaps observational learning is not effective because patients' cognitive distortions are powerful enough to negate any positive effects modeling might provide. For instance, someone with a spider phobia who observes someone else handling a spider might think, "Well, that person isn't harmed by the spider, but there's no guarantee that I'll be so lucky!" Nevertheless, such observational learning can be a helpful addition to CBT (Antony & Swinson, 2000b).

FEEDBACK LOOPS IN TREATMENT: Specific Phobias

When treatment is effective in creating lasting change in one type of factor, it causes changes in the other factors. Consider dental phobia and its treatment. Over 16% of people between the ages of 18 and 26 have significant dental anxiety, according to one survey (Locker, Thomson, & Poulton, 2001). One study examined the effect of a single session of CBT on dental phobia (Thom, Sartory, & Joehren, 2000). The treatment, which consisted of stress management training and imaginal exposure to dental surgery, occurred 1 week prior to the surgery, and patients were asked to practice daily during the intervening week. Another group of people with dental phobia was only given a benzodiazepine 30 minutes before surgery. A third group was given nothing; this was the control group. Both types of treatment led to less anxiety during the dental surgery than was reported by the control group. However, those in the CBT group continued to maintain and show further improvement at a 2-month follow-up: 70% of them went on to have subsequent dental work, whereas only 20% of those in the benzodiazepine group and 10% of the control group did so.

The neuropsychosocial approach leads us to consider how the factors and their feedback loops interact to produce such a specific phobia: The medication, although temporarily decreasing anxiety (neurological factor), did not lead to sustained change either in brain functioning or in thoughts about dental procedures. The CBT, in contrast, targeted psychological factors and also led to changes in a neurological factor—brain functioning associated with decreased anxiety and arousal related to dental surgery. In turn, these changes led to social changes—additional dental work. And the added dental visits presumably led to better health, which in turn affected the participants' view of themselves and their interactions with others. Indeed, if the visits had cosmetic effects (such as a nicer smile), their social benefits would be even more evident. Such feedback loops (see Figure 7.13) underlie the treatment of all specific phobias.

Table 7.12 ▶ Fearful Thoughts Related to Claustrophobia

- Many closed-in places, e.g., elevators, small rooms, do not have enough air.
- I will faint.
- If I go into a closed-in space, e.g., elevator or cave, I will not be able to get out.
- I will not be able to cope if I get stuck in a closed-in place.
- If I get too nervous, I may hurt myself.
- I will embarrass myself.
- I will lose control.
- I cannot think straight in enclosed places.
- I will go crazy.
- I will die.

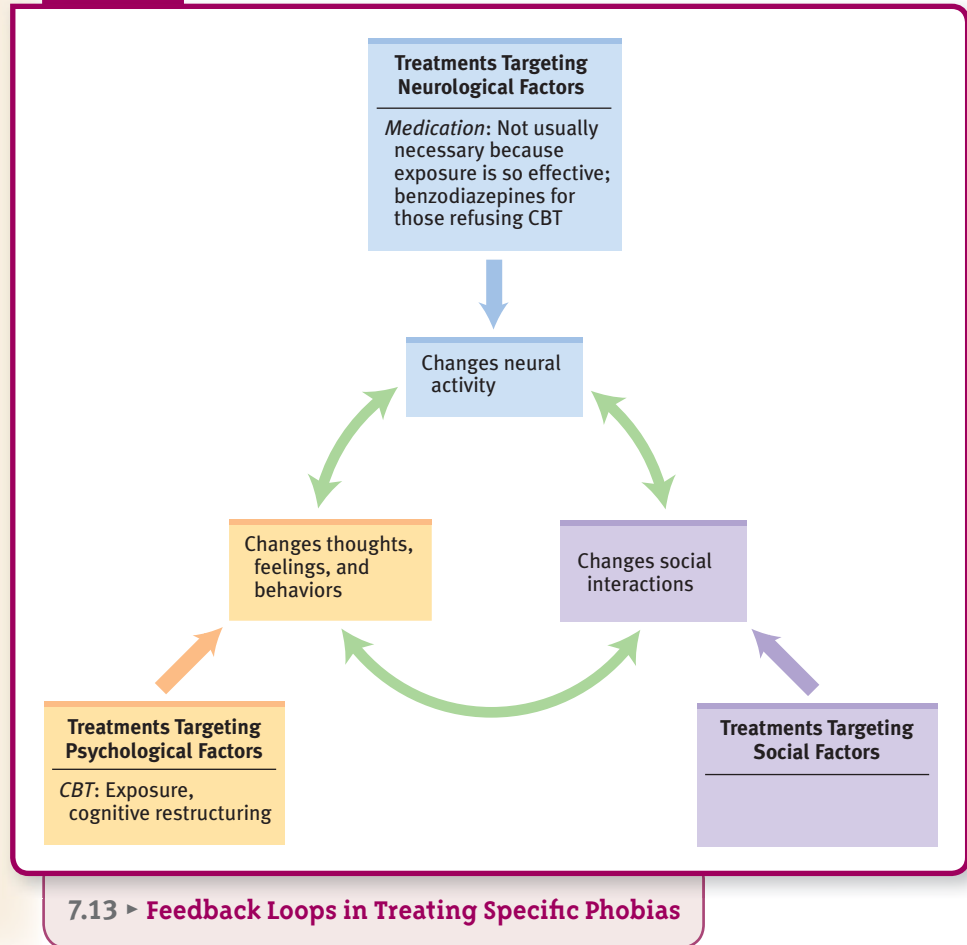

Figure 7.13

Key Concepts and Facts About Specific Phobias

- Specific phobia involves excessive and irrational anxiety or fear related to a specific stimulus and avoidance of the feared stimulus. DSM-IV-TR specifies five types of specific phobias: animal, natural environment, blood-injection-injury, situational, and other.
- People are biologically prepared to develop specific phobias to certain stimuli as well as to resist developing phobias to certain other stimuli.
- Neurological factors, such as an overly reactive amygdala, appear to contribute to specific phobias. Neurotransmitters involved in specific phobias include GABA, serotonin, acetylcholine, and norepinephrine. Research suggests a role for genetics as well: Some genes are associated with specific phobias generally, whereas other genes are associated with particular types of specific phobias.
- Psychological factors that give rise to specific phobias include possibly classical conditioning (but rarely), operant conditioning (negative reinforcement of avoiding the feared stimulus), and cognitive biases related to the stimulus (such as

overestimating the probability that a negative event will occur following contact with the feared stimulus).

- Observational learning—a social factor—can influence what particular stimulus a person comes to fear.
- Treatment for specific phobias can include medication (targeting neurological factors), specifically a benzodiazepine. However, medication is usually not necessary because CBT—the treatment of choice for specific phobia—is extremely effective (targeting psychological factors). CBT—particularly when exposure is part of the treatment—can work in just one session.

Making a Diagnosis

- Reread Case 7.5 about Kevin, and determine whether or not his symptoms met the criteria for specific phobia. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Obsessive-Compulsive Disorder

As we saw earlier, both Howard Hughes and his mother appeared to have a fear of Hughes contracting an illness. After his parents' deaths, Hughes's health concerns increased, and his profound fear of germs—and the rituals and behaviors that he used to limit what he believed were possible routes of contamination—became famous. But the protective rituals and behaviors extended beyond himself (and beyond rational thinking)—he made his aides and associates undertake similar precautions even though they were extreme and didn't, in fact, decrease his risk.

He viewed anyone who came near as a potential germ carrier. Those whose movements he could control—his aides, drivers, and message clerks—were required to wash their hands and slip on thin white cotton gloves . . . before handing him documents or other objects. Aides who bought newspapers or magazines were instructed to buy three copies—Hughes took the one in the middle. To escape dust, he ordered unused windows and doors of houses and cars sealed with masking tape.

(Bartlett & Steele, 1979, p. 175)

And it wasn't only germ prevention that Hughes tried to control. Throughout his life he'd been overly preoccupied with details; at one time or another, he concerned himself with every aspect of his companies—even demanding that employees conduct a detailed study of the vending machines at the Hughes Aircraft Company.

For most of his adulthood, Hughes wrote detailed memos about many things. In his 40s, he started doing so about trivial things. Here's an excerpt from a memo about an upcoming residential move:

Any metal items of value should be protected against deterioration by putting them in a cabinet or a room that is dehydrated and kept dry. This is the new method of preserving metal articles. . . . Any keys found among his things which could not be identified were to be melted down.

(Bartlett & Steele, 1979, p. 176)

Clearly, Hughes's preoccupations and ritualistic behaviors were not “normal.” In fact, his preoccupations and behaviors are symptoms of obsessive-compulsive disorder.

What Is Obsessive-Compulsive Disorder?

Howard Hughes had obsessions and compulsions. **Obsessions** are thoughts, impulses, or images that persist or recur, are intrusive—and therefore difficult to ignore—and are inappropriate to the situation (American Psychiatric Association, 2000). For instance, Hughes had obsessions about germs—his preoccupations about them were intrusive and persistent. Worries about actual problems (such as “How can I pay my bills this month?” or “I don't think I can finish this project by the deadline”) are not considered obsessions.

Whereas obsessions involve thoughts, impulses, and images, compulsions involve behaviors. A **compulsion** is a repetitive behavior (such as avoiding stepping on sidewalk cracks) or mental act (such as silently counting to 10) that a person feels driven to carry out; a compulsion usually corresponds thematically to an obsession. For instance, Howard Hughes was obsessed by the possibility that he might be exposed to germs and was compelled to behave in ways that he believed would protect him from such germs.

The key element of **obsessive-compulsive disorder (OCD)** is one or more obsessions, which may occur together with compulsions (American Psychiatric Association, 2000; see Table 7.13). The obsession can cause great distress and anxiety, despite a person's attempts to ignore or drive out the intrusive thoughts. People with OCD recognize that their obsessive thoughts do not originate from an external

Obsessions

Thoughts, impulses, or images that persist or recur, are intrusive—and therefore difficult to ignore—and are inappropriate to the situation.

Compulsions

Repetitive behaviors or mental acts that a person feels driven to carry out and that usually correspond thematically to an obsession.

Obsessive-compulsive disorder (OCD)

The anxiety disorder characterized by one or more obsessions, which may occur together with compulsions.

OCD can literally be life-threatening. Some people who compulsively hoard have died in fires in their homes. The hoarded objects took up so much space that it was difficult to leave once a fire started, or firefighters had to spend too much time trying to get in to the house (Kaplan, 2007).

Michael Maloney/San Francisco Chronicle/Corb

Table 7.13 ▶ DSM-IV-TR Diagnostic Criteria for Obsessive-Compulsive Disorder**A.** Either obsessions or compulsions:

Obsessions as defined by (1), (2), (3), and (4):

- (1) recurrent and persistent thoughts, impulses, or images that are experienced, at some time during the disturbance, as intrusive and inappropriate and that cause marked anxiety or distress
- (2) the thoughts, impulses, or images are not simply excessive worries about real-life problems
- (3) the person attempts to ignore or suppress such thoughts, impulses, or images, or to neutralize them with some other thought or action
- (4) the person recognizes that the obsessional thoughts, impulses, or images are a product of his or her own mind (not imposed from without, as in thought insertion)

Compulsions as defined by (1) and (2):

- (1) repetitive behaviors (e.g., hand washing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) that the person feels driven to perform in response to an obsession, or according to rules that must be applied rigidly
- (2) the behaviors or mental acts are aimed at preventing or reducing distress or preventing some dreaded event or situation; however, these behaviors or mental acts either are not connected in a realistic way with what they are designed to neutralize or prevent or are clearly excessive.

B. At some point during the course of the disorder, the person has recognized that the obsessions or compulsions are excessive or unreasonable.

Note: This does not apply to children.

C. The obsessions or compulsions cause marked distress, are time consuming (take more than 1 hour a day), or significantly interfere with the person's normal routine, occupational (or academic) functioning, or usual social activities or relationships.**D.** If another Axis I disorder is present, the content of the obsessions or compulsions is not restricted to it (e.g., preoccupation with food in the presence of an Eating Disorders [discussed in Chapter 10]; concern with appearance in the presence of Body Dysmorphic Disorder [Chapter 8]; preoccupation with drugs in the presence of a Substance Use Disorder [Chapter 9]; preoccupation with having a serious illness in the presence of Hypochondriasis [Chapter 8]; preoccupation with sexual urges or fantasies in the presence of a Paraphilia [Chapter 11]; or guilty ruminations in the presence of Major Depressive Disorder [Chapter 6]).**E.** The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

source—for example, the thoughts aren't implanted by aliens from outer space, as some people with psychotic symptoms believe. Instead, they realize that the thoughts arise in their own minds, even though they can't control or suppress the thoughts.

Table 7.14 identifies common types of obsessions and compulsions. Obsessions (listed in the left side of Table 7.14) include preoccupations with *contamination*, *order*, *fear of losing control*, *doubts about whether the patient performed an action*, and *possible needs*. Compulsive behaviors are usually related to an obsession or anxiety associated with a particular situation or stimulus (also listed in Table 7.14) and include *washing*, *ordering*, *counting*, *checking*, and *hoarding* (Mataix-Cols, do Rosario-Campos, & Leckman, 2005). Performing the behavior temporarily prevents or relieves the anxiety. However, compulsions that relieve anxiety can take significant amounts of time to complete—sometimes more than an hour—and often create distress or impair functioning. DSM-IV-TR does not include subtypes of OCD.

Hughes clearly had compulsive symptoms of the contamination-washing type and had the ordering types of obsessions. At one point, he drafted a memo called “Notes on Notes,” providing his assistant and secretaries with exact instructions for their typed notes:

Table 7.14 ► Common Types of Obsessions and Compulsions

Type of Obsession	Examples of obsessions: People with OCD may be preoccupied with anxiety-inducing thoughts about . . .	Type of Compulsion	Examples of compulsions: In order to decrease anxiety associated with an obsession, people may repeatedly be driven to . . .
Contamination	germs, dirt	Washing	wash themselves or objects in order to minimize any imagined contamination
Order	objects being disorganized, or a consuming desire to have objects or situations conform to a particular order or alignment	Ordering	order objects, such as canned goods in the cupboard, so that everything in the environment is “just so” (and often making family members and friends maintain this order)
Losing control	the possibility of behaving impulsively or aggressively, such as yelling during a funeral	Counting	count in response to an unwanted thought, which leads to a sense that the unwanted thought is neutralized (for instance, after each thought of blurring out an obscenity, methodically counting to 50)
Doubt	whether an action, such as turning off the stove, was performed	Checking	check that they did, in fact, perform a behavior about which they had doubts (such as repeatedly checking that the stove is turned off)
Possible need	the extremely remote likelihood that they will need a particular object at some undetermined point in the future as part of some unknown need (for instance, that they might need to look up something in today’s newspaper in a few years)	Hoarding	hoard or collect objects that have no purpose (such as years’ worth of newspapers) to the point where the behavior is clearly maladaptive (when piles of newspapers interfere with walking freely from room to room)

The word “shall” shall be used throughout instead of “will” in the third person singular and plural, making all sentences in the imperative rather than the indicative.

The infinitive verb shall not be used to express a major thought, except as an auxiliary to a main verb.

No changes or marks shall be made on the original pencil version.

The numbering system set forth in the notes shall not be a criterion for any future numbering system.

(Bartlett & Steele, 1979, p. 133)

Like the other anxiety disorders we’ve discussed, OCD often involves an unrealistic or disproportionate fear—in this case, of adverse consequences if the compulsive behavior is not completed. For instance, someone who hoards newspapers may be afraid that if she did not keep the papers, she would be unable to find an article that might later be crucial in some unforeseen medical or legal matter. Or someone with an obsession about contamination, like Hughes, fears that if all germs aren’t washed off, he will die of some disease. Additional facts about OCD are provided in Table 7.15, and Case 7.6 describes one woman’s experience with OCD.

CASE 7.6 ► FROM THE INSIDE: Obsessive-Compulsive Disorder

For someone with OCD, just getting up in the morning and getting dressed can be filled with trials and tribulations:

Should I get up? It’s 6:15. No, I better wait till 6:16, it’s an even number. OK, 6:16, now I better get up, before it turns to 6:17, then I’d have to wait till 6:22.

OK, I’ll get up, OK, I’m up, WAIT! I better do that again. One foot back in bed, one foot on the floor, now the other foot in bed and the opposite on the floor. OK. Let’s take a shower, WAIT! That shoe on the floor is pointing in the wrong direction, better fix it. Oops, there’s a piece of lint there, I better not set the shoe on top of it. . . . OH, JUST TOUCH THE SHOE TWICE AND GET OUTTA HERE!

continued on next page

All right, I got to the bedroom door without touching anything else, but I better step through and out again, just to be sure nothing bad will happen. THERE, THAT WAS EASY! Now to the bathroom. I better turn that light on, NO, off, NO, on, NO, off, NO, on, KNOCK IT OFF! All right, I'm done using the toilet, better flush it. OK, now spin around, wait for the toilet to finish a flush, now touch the handle, now touch the seat, remember you have to look at every screw on the toilet seat before you turn around again. OK, now turn around and touch the seat again, look at all the screws again. OK, now close the cover.

OK, let's pick out some clothes in the bedroom. First, I have to get out of the bathroom. Step in, step out, step in, step out, now look at all the hinges on the bathroom door. Do this on each step, both in and out of the bathroom.

OK, let's get some underwear. I want to wear the green ones because they fit the best, but they're lying on top of the T-shirt my grandmother gave me, and her husband (my grandfather) died last year, so I better wash those again before I wear them. If I wear them, something bad might happen.

(Steketee & White, 1990, pp. 4–5)

Understanding Obsessive-Compulsive Disorder

OCD can be understood by considering neuropsychosocial factors and their interactions. As with social phobia, neurological, psychological, and social factors influence one another. With OCD, however, social factors have less influence than neurological and psychological factors do. Howard Hughes had neurological and psychological vulnerabilities for the disorder that may have been exacerbated by psychological and social factors. Let's examine these factors in more detail.

Table 7.15 ► Obsessive-Compulsive Disorder Facts at a Glance

Prevalence

- Approximately 2–3% of Americans will develop OCD at some point in their lives (Burke & Regier, 1994), with generally similar prevalence rates worldwide (Horwath & Weissman, 2000).

Comorbidity

- Over 90% of those with OCD have another Axis I disorder, with the most frequent categories of comorbid disorders being mood disorders (81%) and other anxiety disorders (53%) (LaSalle et al., 2004). Eating disorders and some personality disorders are also relatively commonly diagnosed as comorbid with OCD.

Onset

- Among males with OCD, symptoms typically begin to emerge between the ages of 6 and 15.
- Among females, symptoms typically emerge between the ages of 20 and 29.

Course

- Symptoms typically build gradually until they reach a level that meets the diagnostic criteria. Over the course of a lifetime, symptoms wax and wane, becoming particularly evident in response to stress.

Gender Differences

- Men and women have an equal risk of developing OCD.

Cultural Differences

- Although the prevalence rates of OCD and the types of symptoms are about the same across cultures, the particular content of symptoms may differ as a function of cultural or religious prohibitions (Matsunaga et al., 2007; Millet et al., 2000).

Source: Unless otherwise noted, information in the table is from American Psychiatric Association, 2000.

Neurological Factors

Researchers have made much progress in understanding the neurological underpinnings of OCD. In the following sections we'll review how brain circuits have gone awry in this disorder, resulting in a loop of neural activity that may produce intrusive thoughts (obsessions) and lead one to repeat the same behavior over and over (compulsions); we'll also see that abnormalities in how neurotransmitters function (serotonin) play a role in this disorder. However, although genes also play a role, the genetic story is complex: Genes predispose people toward developing this disorder, but apparently by having an effect on anxiety disorders in general—not OCD in particular.

Brain Systems

When the frontal lobes trigger an action, there is feedback from the basal ganglia—and sometimes this feedback sets up a loop of repetitive activity, as shown in Figure 7.14 (Breiter et al., 1996; Jenike, 1984; Rauch et al., 1994, 2001). Many researchers now believe that this neural loop plays a key role in obsessive thoughts, which intrude and cannot be stopped easily. Performing a compulsion might temporarily stop the obsessive thoughts by reducing the repetitive neural activity (Insel, 1992; Jenike, 1984; Modell et al., 1989). (But soon after the compulsive behavior stops, the obsessions typically resume.)

Consistent with these ideas, Rapoport (1991) proposed that OCD symptoms can be caused by dysfunctional connections among the frontal lobes, the thalamus, and the basal ganglia (see Figure 7.14). Much research has focused on possible abnormalities in the basal ganglia and frontal lobes

Figure 7.14

7.14 ► The Neural Loop That May Underlie Obsessive Thoughts The basal ganglia, the thalamus, and the frontal lobes are part of a neural loop of repeating brain activity associated with OCD.

in particular (Insel, 1992; Pigott, Myers, & Williams, 1996; Saxena & Rauch, 2000). In fact, as predicted by the theory, both the frontal cortex (especially the orbital frontal cortex—the lower parts of the cortex, behind the eyes) and the basal ganglia function abnormally in OCD patients (Baxter, 1992; Berthier et al., 2001; Saxena et al., 1998). This abnormal functioning could well prevent the frontal lobe from cutting off the loop of repetitive neural activity, as it appears to do in normal people.

Researchers have also suggested that OCD is associated with larger amounts of gray matter in the frontal lobes and smaller amounts in the posterior portions of the brain (Kim et al., 2001). Such structural abnormalities are consistent with the unusually large amount of activity in patients' frontal regions when they see a stimulus that provokes the OCD-related thoughts and behaviors (Adler et al., 2000). Furthermore, these patients have impaired visual-spatial abilities, which rely on similar areas of the brain (Micalef & Blin, 2001).

However, not all studies have found such brain abnormalities (Baxter, Schwarz, & Guze, 1991), which may suggest that there is more than one way OCD can arise (Hollander, Liebowitz, & Rosen, 1991). In fact, researchers have found that many (but not all) patients with OCD had an abnormal birth, epilepsy, head trauma, or infection of the brain or the membranes that cover it. For example, as we saw in Chapter 5, when children rapidly develop symptoms of OCD, the cause may be a particular type of streptococcal infection that leads to a disorder in the immune system, which is called *pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection*. This disorder affects the basal ganglia (Swedo et al., 1998). Symptoms of OCD disappear when the children take the appropriate antibiotics.

AP Photo/Matt Dunham

Soccer star David Beckham suffers from OCD. His symptoms focus on ordering: "I have to have everything in a straight line or everything has to be in pairs. . . . I'll go into a hotel room. Before I can relax I have to move all the leaflets and all the books and put them in a drawer. Everything has to be perfect." (Dolan, 2006).

Neural Communication: Serotonin

OCD appears to arise in large part because brain circuits don't operate normally, but why don't they? One reason may be that people with OCD have too little of the neurotransmitter serotonin, which allows unusual brain activity to occur (Mundo et al., 2000). And, in fact, medications that increase the effects of serotonin (such as Prozac), often by preventing reuptake of this neurotransmitter at the synapse (see Chapter 6), can help to treat OCD symptoms (Greenberg, Altemus, & Murphy, 1997; Micallef & Blin, 2001; Thomsen, Ebbesen, & Persson, 2001). However, in spite of the efficacy of such medication, several studies have not been able to document that patients with OCD have abnormally low amounts of serotonin (Delgado & Moreno, 1998; Insel & Winslow, 1990). Drugs that increase the effects of serotonin may affect the symptoms of OCD indirectly, perhaps by decreasing activity in the neural loop that involves the frontal cortex and the basal ganglia (Saxena & Rauch, 2000).

In addition, it is possible that different varieties of OCD arise for different reasons. For example, patients who need to wash their hands repeatedly may have too little serotonin, whereas patients who have intense ordering obsessions may have had brain damage (Pigott, 1996). Moreover, there is a hint that different mechanisms may cause early-onset OCD (which develops before age 10) and later-onset OCD, as early-onset OCD responds less well to drugs that affect serotonin (Erzegovesi et al., 2001; Rosario-Campos et al., 2001).

Genetics

Twin studies have shown that if one monozygotic (identical) twin has OCD, the other is very likely (65%) to have it. As should be expected if this high rate reflects common genes, the rate is lower (only 15%) for dizygotic twins (Pauls, Raymond, & Robertson, 1991). Moreover, as you would expect from the results of the twin studies, OCD is more common among relatives of OCD patients (10.3% of whom also have OCD) than among relatives of control participants (of whom only 2% also have OCD) (Pauls et al., 1995).

However, although family studies have documented a genetic contribution to OCD, the link is neither simple nor straightforward: Members of the family of a person with OCD are more likely than other people to have an anxiety disorder, but that disorder need not be OCD specifically (Black et al., 1992; Smoller, Finn, & White, 2000; Torgersen, 1983).

Author Emily Colas, who has OCD, recounts her mother's struggle with symptoms of the disorder:

I used to get frustrated at bedtime. My mother would sit on the edge of my bed, tuck me in, and kiss me good-night. Then she'd walk to the door and with her middle finger flick the light switch off. The hall light was on so I could see mom standing there a few minutes later still stroking the switch that was clearly by that time down. I'd yell "It's off!" to get her out of my room. She'd look back at me and then turn her head away, silently shut my door, and leave. Fifteen years later she explained to me that she knew the light was in fact off, but felt compelled to keep flicking the switch, in multiples of four, until it felt "right."

(Colas, 1998, p. 31)

When many people first learn about OCD, they recognize tendencies they've noticed in themselves. If you've had this reaction while reading this section, you shouldn't worry: OCD may reflect extreme functioning of brain systems that function the same way in each of us to produce milder forms of such thinking. According to this view, OCD is not a qualitatively distinct disorder, with brain systems producing abnormal types of outputs (the way hallucinations may arise in some psychotic disorders), but rather is just one end of a continuum—with "normal" anchoring the other end. In fact, researchers found that the relatives of OCD patients were more likely than controls to have both OCD and OCD-like symptoms that were *subclinical* (not severe enough to qualify as the disorder) (Pauls et al., 1995). With subclinical symptoms, the brain produces the same kinds of thoughts, impulses, and images as found in OCD, but not frequently or strongly enough to disrupt daily life.

Psychological Factors

Psychological factors that help to explain OCD focus primarily on the way that operant conditioning affects compulsions and on the process by which normal obsessional thoughts become pathological.

Behavioral Explanations: Operant Conditioning and Compulsions

Compulsive behavior can provide short-term relief from anxiety that is produced by an obsession. Operant conditioning occurs when the behavior is negatively reinforced: Because it (temporarily) relieves the anxiety, it is more likely to recur when the thoughts arise again. All of Howard Hughes's various eccentric behaviors—his washing, his precautions against germs, his exerting control over the minute specifics of his memos (in “Notes on Notes”), his hoarding of newspapers and magazines—temporarily relieved his anxiety.

Cognitive Explanations: Obsessional Thinking

If you've ever had a crush on someone or been in love, you may have spent a lot of time thinking about the person—it may have even felt like an obsession. Such obsessions arise surprisingly frequently (Weissman et al., 1994), but they don't usually develop into a disorder. One theory about how a normal obsession becomes part of OCD is that the person decides that his or her thoughts refer to something unacceptable, such as killing someone or, as was the case with Howard Hughes, catching someone else's illness (Salkovskis, 1985). These obsessive thoughts, which the individual believes imply some kind of danger, lead to very uncomfortable feelings. Mental or behavioral rituals arise in order to reduce these feelings. A related theory is that for some people who develop OCD, a disturbing thought is the moral equivalent of actually performing the act, which leads to greater distress in response to the initial obsession (Rachman, 1997; Shafran, Thordarson, & Rachman, 1996). Both theories contrast a normal response to “unacceptable” thoughts (an awareness that such thoughts don't need to be controlled and an ability to let them fade from consciousness) with the belief of OCD patients that such thoughts must be controlled—and trying to do so amplifies the thoughts (Tolin, Worhunsky, & Maltby, 2006).

Consistent with this theoretical approach, researchers have found that some mental processes function differently in people with OCD than in people without the disorder. In particular, such patients are more likely to pay attention to and remember threat-relevant stimuli, and their processing of complex visual stimuli (as, for example, is necessary to decide whether an object has been touched by a dirty or clean tissue among people with contamination fears) is impaired (Constans et al., 1995; Muller & Roberts, 2005; Radomsky, Rachman, & Hammond, 2001). Such processing may make threatening stimuli easier to remember and harder to ignore, which keeps them in the patients' awareness longer (Muller & Roberts, 2005). Studies of memory also find that those with the checking type of OCD and those in a control group had equally accurate memories, but the OCD patients had less *confidence* in the accuracy of their recognition memories (MacDonald et al., 1997; McNally & Kohlbeck 1993; Muller & Roberts, 2005). Thus, because they are more likely to doubt their memories, they are more likely to want to go back and check.

Social Factors

Two types of social factors can contribute to OCD. One is stress, which can influence the onset and course of the disorder; the other is culture, which can influence the particular content of symptoms.

Stress

The onset of OCD often follows a stressor, and the severity of the symptoms is often proportional to the severity of the stressor (Turner & Beidel, 1988), which might range from taking a vacation at one end to the death of a family member at the other. However, such findings are not always easy to interpret. For example, one study found that people with more severe OCD tend to have more kinds of family

stress and are more likely to be rejected by their families (Calvocoressi et al., 1995). Note, however, that the direction of causation is not clear: Although stress in the family may cause the greater severity of symptoms, it is also possible that the more severe symptoms led the families to reject the patients. In fact, a more recent study found that the more severe the patient's OCD symptoms, the less hopeful and more depressed were family members (Geffken et al., 2006). People with OCD often impose various restrictions on the behavior of friends and family members to ensure that it conforms to the patient's "rules," as Hughes did. For instance, someone who compulsively checks that doors and windows are locked may demand that family members similarly—and repeatedly—check the locks throughout the day.

Stress greatly affected the course of Hughes's symptoms. For much of his 20s, 30s, and early 40s, he was able to function relatively well, given the freedom his wealth and position provided. Although he was often preoccupied with work—staying up for 40 hours at a time to work on a film or on a design for a plane—he was able to keep his obsessions and compulsions at bay well enough to do his work. However, there were occasional periods of time when the external demands of his life became intense—deadlines, fights with associates, or legal problems—and his symptoms worsened. During one particularly stressful period in his late 30s, "Hughes began repeating himself at work and in casual conversations. In a series of memoranda on the importance of letter writing, he dictated, over and over again, 'a good letter should be immediately understandable . . . a good letter should be immediately understandable . . . a good letter should be immediately understandable . . .'" (Bartlett & Steele, 1979, p. 132).

By the time Hughes was in his 50s, however, the stressors increased and his functioning diminished. There were periods when he was so preoccupied with his germ phobia that he couldn't pay attention to anything else. At other times, his symptoms ebbed enough that he was able to focus somewhat on running his empire. But he couldn't reliably attend to the day-to-day demands of his businesses.

Culture

Different countries have about the same prevalence rates of OCD, although culture (Weissman et al., 1994) and religion can help determine the particular content of some obsessions or compulsions. For instance, religious obsessions and praying compulsions are more common among Turkish men than French men (Millet et al., 2000) and more common among Brazilians than Americans or Europeans (Fontenelle et al., 2004). And a devoutly religious patient's symptoms can relate to the specific tenets and practices of his or her religion (Shooka et al., 1998): Someone who is Catholic may have obsessional worries about having impure thoughts or feel a compulsion to go to confession multiple times each day. In contrast, devout Jews or Muslims may have symptoms that focus on extreme adherence to religious dietary laws.

FEEDBACK LOOPS IN ACTION:

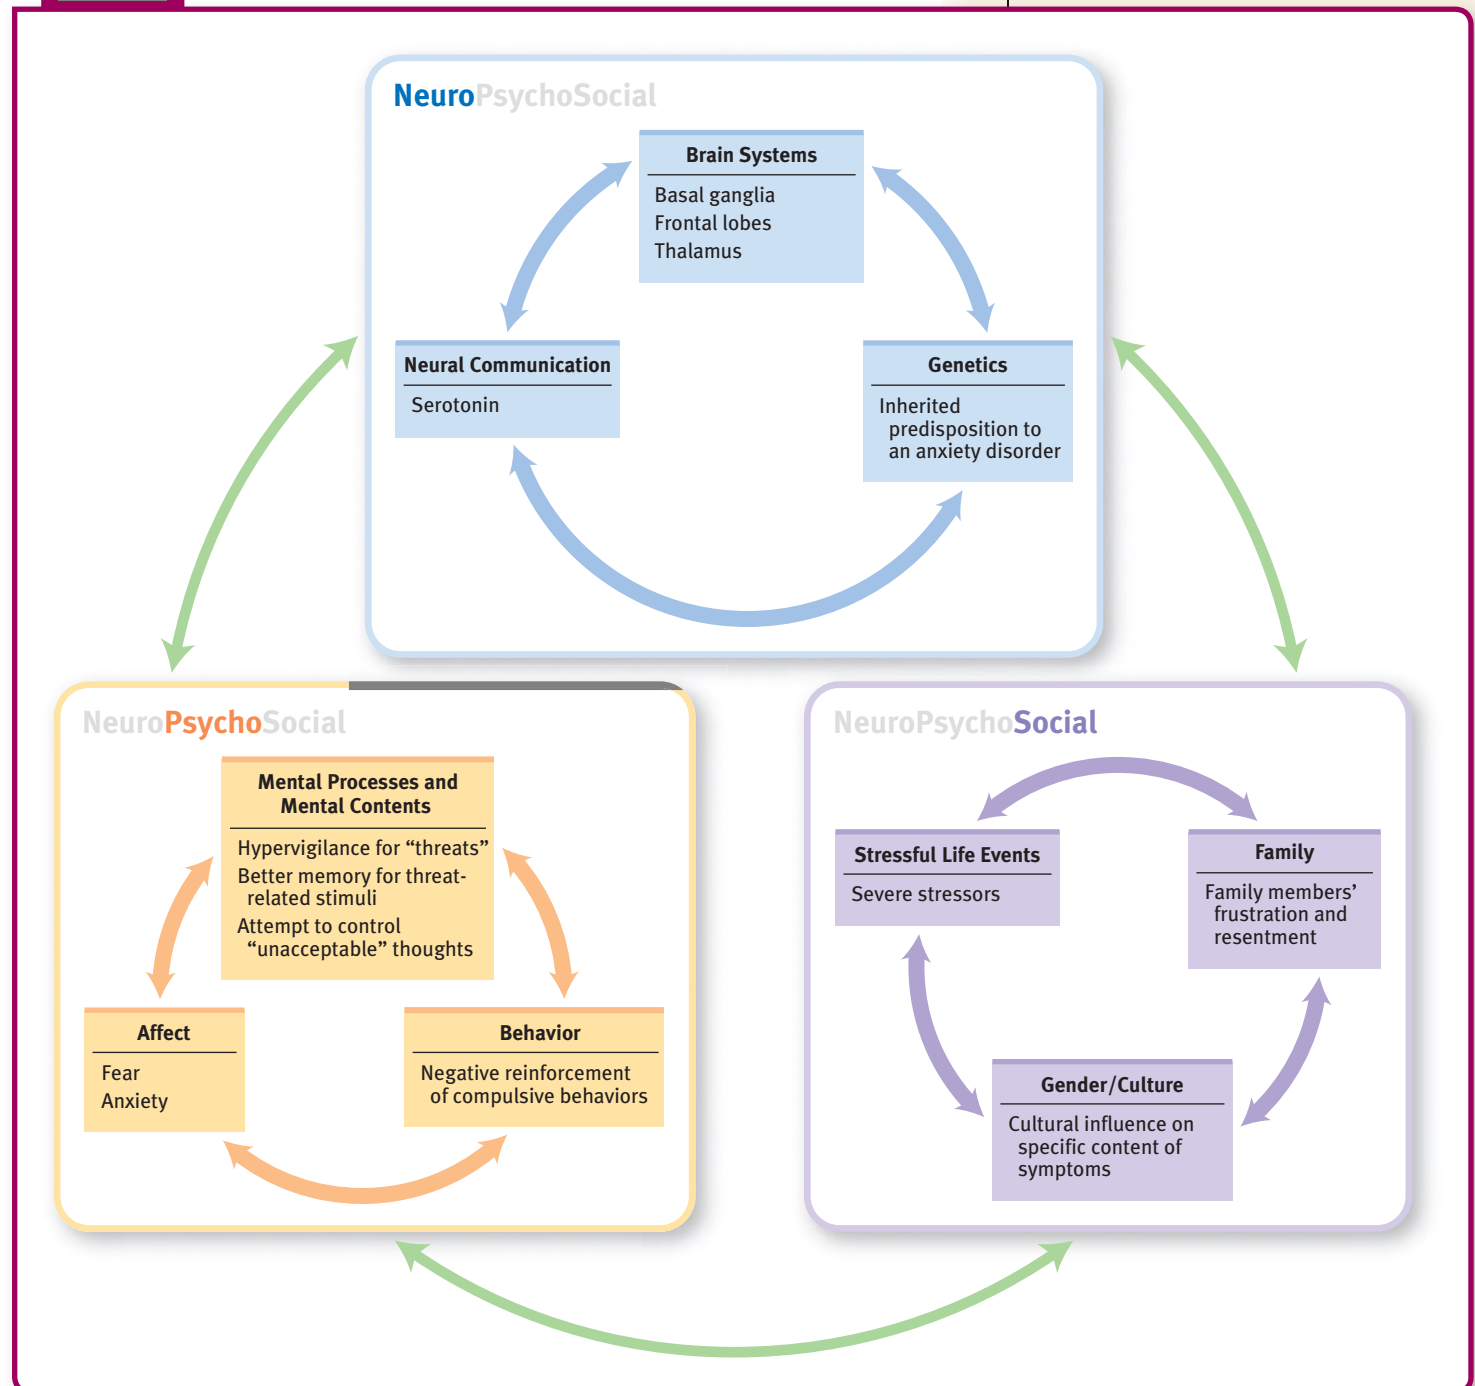

Understanding Obsessive-Compulsive Disorder

One neurological underpinning of OCD appears to be a tendency toward increased activity in the neural loop that connects the frontal lobes and the basal ganglia (neurological factor). A person with such a neurological vulnerability might learn early in life to regard certain thoughts as dangerous because they can lead to obsessions. When these thoughts appear later in life at a time of stress, someone who is vulnerable may become distressed and anxious about the thoughts and try to suppress them. But a conscious attempt to suppress unwanted thoughts often has the opposite effect: The unwanted thoughts become more likely to persist (Salkovskis & Campbell, 1994; Wegner et al., 1987). Thus, the intrusive thoughts cause additional distress, and so the person tries harder to suppress them, creating a reinforcing cycle (psychological factor).

The content of a person's unwanted thoughts determine the extent to which those thoughts are unacceptable. When a person wants to suppress the unwanted thoughts, he or she develops rituals and avoidance behaviors to increase a sense of

control and decrease anxiety; these behaviors temporarily lessen anxiety and are thus reinforced. Yet the thoughts cannot be fully controlled and become obsessive; the obsessions and compulsions impair functioning and can affect relationships as well. The person with OCD may expect family members and friends to conform to compulsive guidelines; these people and others can become frustrated and dismayed at the patient's rituals and obsessions (social factors). Figure 7.15 illustrates these factors and feedback loops.

Figure 7.15

7.15 ► Feedback Loops in Action: Obsessive-Compulsive Disorder

Treating Obsessive Compulsive Disorder

The primary targets of treatment for OCD are usually either neurological or psychological factors. In Hughes's case, there was no one in his life with the clout and concern who could tell the powerful man that he needed help. As biographers Barlett and Steele (1979) note, his living situation was like a mental institution, but it was run by the patient, and no one was telling him that he had problems. His aides carried out whatever compulsive demands Hughes made, never challenging him about the irrationality of his orders.

Targeting Neurological Factors: Medication

An SSRI is usually the type of medication used first to treat OCD: *paroxetine* (Paxil), *sertraline* (Zoloft), *fluoxetine* (Prozac), *fluvoxamine* (Luvox), or *citalopram* (Celexa) (Soomro et al., 2008). OCD can also be treated effectively with the TCA *clomipramine* (Anafranil), although a higher dose is required than that prescribed for depression or other anxiety disorders (Rosenbaum et al., 2005). People who develop OCD in childhood are less likely to respond well to clomiprimine or to other antidepressants (Rosario-Campos et al., 2001). Hughes's use of codeine and Valium did not appear to diminish his obsessions and compulsions in any significant way; in fact, such medications are not routinely prescribed for OCD. However, medication alone is not as effective as medication combined with behavioral treatment, such as exposure and response prevention (discussed in Chapter 4 and in the next section). As with other anxiety disorders, when the medication is discontinued, OCD symptoms usually return (Foa et al., 2005).

If medication and behavioral treatments don't help a person who has *severe* OCD, he or she may receive transcranial magnetic stimulation (TMS) or neurosurgery (see Chapter 4). TMS involves delivering a series of very fast pulses of a very strong magnetic field to part of the brain, which disrupts neural activity. However, the jury is still out on the value of this treatment for this disorder. Neurosurgery, used as a last resort for cases that do not respond to less drastic treatment, is aimed at disrupting the circuit (involving the frontal lobe and the basal ganglia, described earlier) that apparently underlies the obsessions and compulsions that characterize OCD (Greenberg, Murphy, & Rasmussen, 2003; Husted & Shapira, 2004; Mantovani et al., 2006; Pallanti, Hollander, & Goodman, 2004).

Targeting Psychological Factors

Treatment that targets psychological factors focuses on decreasing the compulsive behaviors and the obsessional nature of the thoughts. Both behavioral and cognitive methods are effective (Cottraux et al., 2001), and treatment may combine both types of methods (Franklin et al., 2002).

Behavioral Methods: Exposure With Response Prevention

Patients with OCD often undertake exposure with response prevention (see Chapter 4) as a behavioral treatment. The patient is exposed to the feared stimulus (such as touching dirt) or the obsessive thought (such as the idea that the stove was left on) and is prevented from engaging in the usual compulsion or ritual. For instance, if someone were afraid of touching dirt, she would touch dirt but would not then wash her hands. Through exposure with response prevention, patients learn that nothing bad happens if they don't perform their compulsive behavior; the anxiety is lessened without resorting to the compulsion, their fear and arousal subside, and they experience mastery. They survived the anxiety and exerted control over the compulsion. When patients successfully respond differently to a feared stimulus, this mastery over the compulsion gives them hope and motivates them to continue to perform the new behaviors.

Although exposure treatment for OCD can be very helpful, not everyone is willing to use this form of treatment. Confronting a feared stimulus is, well, frightening! Medication may help such people when beginning exposure treatment—it can help them tolerate the anxiety that arises. Then, as the exposure treatment progresses,

the medication is tapered off and the behavioral method is continued. This form of combined treatment may help minimize relapse when medication is stopped, compared to medication alone (Ellison & McCarter, 2002; Foa et al., 2005).

Cognitive Methods: Cognitive Restructuring

The goal of cognitive methods is to reduce the irrationality and frequency of the patient's intrusive thoughts and obsessions (Clark, 2005). Cognitive restructuring focuses on assessing the accuracy of these thoughts, making predictions based on them ("If I don't go back to check the locks, I will be robbed"), and testing whether these predictions come to pass.

Although CBT for OCD hadn't been sufficiently developed during Hughes's lifetime, consider how it might have been used: There were periods when Hughes daily and "painstakingly used Kleenex to wipe 'dust and germs' from his chair, ottoman, side table, and telephone. Sometimes he spent hours methodically cleaning the telephone, going over the earpiece, mouthpiece, base, and cord with Kleenex, repeating the cleaning procedure again and again, tossing the used tissues into a pile behind his chair" (Bartlett Steele, 1979, p. 233). At the same time, though, he didn't have his sheets changed for months at a time; to make the sheets last longer, he laid paper towels over them and slept on those. Moreover, he bathed only a few times a year. Clearly, such behavior was at odds with rational attempts to protect against germs. CBT would have focused on his overestimation of the probability of contracting an illness and the irrationality of his precautions.

Targeting Social Factors: Family Therapy

Although psychological or neurological factors are the primary targets of treatment for OCD, in some cases, social factors may also be addressed, for example, through family therapy or consultation with family members. This aspect of treatment educates family members about the patient's treatment and its goals and helps the family function in a more normal way. Family members and friends may have spent years conforming their behavior to the patient's illness (e.g., using clean tissues when handing an object to the patient), and they may be afraid to change their own behavior as the patient gets better, for fear of causing a relapse.

FEEDBACK LOOPS IN TREATMENT: Obsessive-Compulsive Disorder

As we've seen, medication can be effective in treating the symptoms of OCD (at least as long as the patient continues to take it). Medication works by changing neurochemistry, which in turn affects thoughts, feelings, and behaviors. We've also seen that CBT is effective. How does CBT have its effects? Could it be that therapy changes brain functioning in the same way that medication does? Until recently, such questions could not be answered. But neuroimaging has made it possible to begin to understand the positive effects of both medication and CBT on people with OCD. The neuropsychosocial approach leads us to examine the types of factors and their feedback loops (see Figure 7.16).

For example, in one study, researchers used PET scans to assess brain functioning in two groups of OCD patients. One group was given behavior therapy and the other group was given the SSRI fluoxetine (Prozac), which can reduce OCD symptoms. Both behavior therapy and Prozac decreased activity in a part of the basal ganglia that is involved in automatic behaviors (the right caudate). Prozac also affected activity in two parts of the brain involved in attention: the thalamus and the anterior cingulate (Baxter et al., 1992). Later research replicated the effects of behavior therapy on the brain (Schwartz et al., 1996).

In short, behavioral therapy or CBT changes the brain (neurological factor). As the patient improves, personal relationships change (social factor): The time and energy that had gone into the compulsions can be diverted to relationships. Moreover, the patient experiences mastery over the symptoms and develops hope and a new view of himself or herself (psychological factors). In turn, this makes the patient more willing to continue therapy, which further changes the brain, and so on, in a happy cycle of mutual feedback loops among neurological, psychological, and social factors.

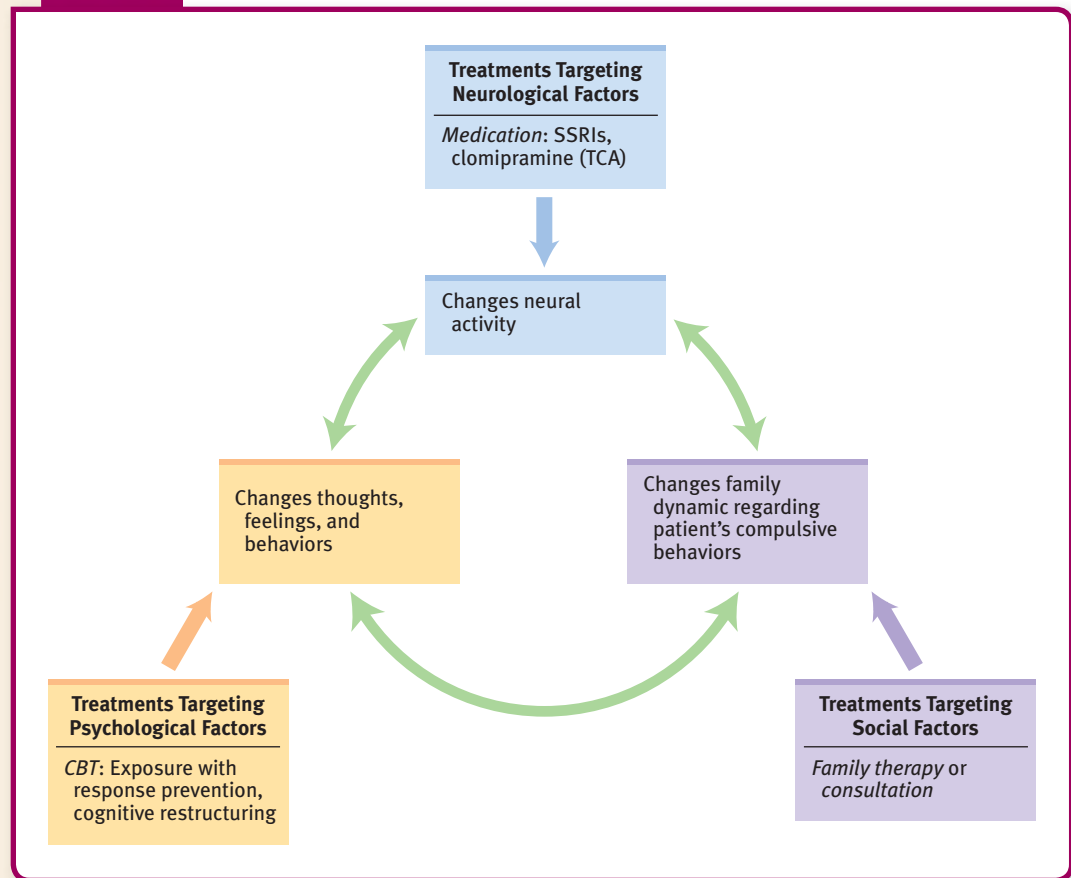

Figure 7.16

7.16 ► Feedback Loops in Treating Obsessive-Compulsive Disorder

Key Concepts and Facts About Obsessive-Compulsive Disorder

- OCD is marked by persistent and intrusive preoccupations and—in most cases—repetitive, compelled behaviors that usually correspond to the obsessions. Although people with OCD recognize that their obsessions are irrational, they cannot turn off the preoccupying thoughts; they feel driven to engage in the compulsive behaviors, which provide only brief respite from the obsessions.
- Common obsessions include anxiety about contamination, order, losing control, doubts, and possible future need. Common compulsions include washing, ordering, counting, checking, and hoarding or collecting.
- Neurological factors associated with OCD include disruptions in the normal activity of the frontal lobes, the thalamus, and the basal ganglia; the frontal lobes do not turn off activity of the neural loop among these three brain areas, which may lead to the persistent obsessions. Lower than normal levels of serotonin also appear to play a role, although this may be more directly related to some types of OCD than others. Genes appear to make some people more vulnerable to anxiety disorders in general—not necessarily to OCD specifically.
- Psychological factors that may underlie OCD include negative reinforcement of the compulsive behavior, which temporarily relieves the anxiety that arises from the obsession. In addition, normal preoccupying thoughts may become obsessions when the thoughts are deemed “unacceptable” and hence require controlling. In turn, the thoughts lead to anxiety, which is then relieved by a mental or behavioral ritual. Like people with other anxiety disorders, people with OCD have cognitive biases related to their feared stimuli, in this case, regarding the theme of their obsessions.
- Social factors related to OCD include socially induced stress, which can influence the onset and course of the disorder, and culture, which can influence the particular content of obsessions and compulsions.

- Medication (such as an SSRI or clomipramine) is the treatment for OCD that directly targets neurological factors. The primary treatment for OCD—exposure with response prevention—directly targets psychological factors. Cognitive restructuring to reduce the irrationality and frequency of the patient’s intrusive thoughts and obsessions may also be employed. Family education or therapy, targeting social factors, may be used as an additional treatment to help the patient’s family function in a more normal way.

Making a Diagnosis

- Reread Case 7.6 about the woman who took a long time to get out of bed and get dressed in the morning, and determine whether or not her symptoms meet the criteria for obsessive-compulsive disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Posttraumatic Stress Disorder

Within a 15-year span, Howard Hughes suffered more than his share of brushes with death—of his own and that of other people. He ran over and killed a pedestrian. He was the pilot in three plane accidents: In the first one, his cheekbone was crushed; in the second, two of his copilots died; in the third, he sustained such extensive injuries to his chest that his heart was pushed to the other side of his chest cavity and he wasn’t expected to live through the night. Hughes did survive, but he clearly had endured a highly traumatic event.

Some people who experience a traumatic event go on to develop a *stress disorder*, which according to DSM-IV-TR (American Psychiatric Association, 2000) is marked by three types of persistent symptoms:

- *Reexperiencing the traumatic event.* Reexperiencing may involve flashbacks that can include illusions, hallucinations, or a sense of reliving the experience, as well as intrusive and distressing memories, dreams, or nightmares of the event.
- *Avoidance.* The individual avoids anything related to the trauma. The person may also experience a general emotional *numbness*.
- *Increased arousal and anxiety.* Arousal and anxiety symptoms include difficulty sleeping, hypervigilance, and a tendency to be easily startled (referred to as a heightened startle response).

DSM-IV-TR includes two types of stress disorders: *acute stress disorder*, which is the diagnosis when the above symptoms emerge within 4 weeks of a traumatic event and last less than 1 month and the person also experiences dissociation (to be discussed later); in contrast, *posttraumatic stress disorder (PTSD)* is the diagnosis if the symptoms last more than 1 month.

In this section we first explore the difference between everyday stress and the traumatic stress associated with stress disorders and then discuss posttraumatic stress disorder in detail. After that, we turn to the factors that give rise to stress disorders. At the end of the section, we explore treatments for posttraumatic stress disorder.

Stress Versus Traumatic Stress

Most people would agree that Hughes experienced a traumatic event when his airplane crashed and he was severely injured. But where is the line that separates a stressful event from a traumatic one? According to DSM-IV-TR, stress turns into traumatic stress when “the person has been exposed to a traumatic event in which both of the following were present:

1. the person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others [and]

Howard Hughes survived several plane crashes, including the one shown above, and he ran over and killed a pedestrian (Fowler, 1986); any of these events would have been traumatic for most people. Some people who experience a traumatic event develop a stress disorder: acute stress disorder or posttraumatic stress disorder.

2. the person's response involved intense fear, helplessness, or horror. Note: In children, this may be expressed instead by disorganized or agitated behavior." (American Psychiatric Association, 2000)

This definition has two components—the traumatic event itself, and the person's response to it. Let's examine both components.

Traumatic events are beyond the normal stressful events we all regularly encounter. Examples of traumatic events range from large-scale catastrophes with multiple victims (such as disasters and wars) to unintended acts or situations involving fewer people (such as motor vehicle accidents and life-threatening illnesses) to events that involve intentional and personal violence, such as rape and assault (Briere, 2004). Table 7.16 lists examples of various types of traumatic events. Traumatic events are relatively common: up to 30% of people will experience some type of disaster in their lifetime, and 25% have experienced a serious car accident (Briere & Elliott, 2000). Note that according to the DSM-IV-TR definition, emotional abuse is not a traumatic event, because it does not involve actual or threatened physical injury or death.

Several factors can affect whether a stress disorder will develop following a traumatic event:

- *The kind of trauma.* Trauma involving violence—particularly intended personal violence—is more likely to lead to a stress disorder than are natural disasters (Breslau et al., 1998; Briere & Elliott, 2000; Copeland et al., 2007; Dikel, Engdahl, & Eberly, 2005; Resnick et al., 1993).
- *The severity of the traumatic event, its duration, and its proximity* (American Psychiatric Association, 2000). Depending on the specifics of the traumatic event, those physically closer to it—nearer to the primary area struck by a tornado, for example—are more likely to develop a stress disorder (Blanchard et al., 2004; Middleton, Willmer, & Simmons, 2002), as are those who have experienced multiple traumatic events (Copeland et al., 2007). For instance, Vietnam veterans were more likely to develop PTSD if they had been wounded or if they spent more time in combat (Gallars et al., 1988; King et al., 1999). The same is true of veterans returning from Iraq and Afghanistan: Soldiers who were involved in combat were up to three times more likely to develop PTSD than soldiers who were not exposed to combat (Levin, 2007; Smith et al., 2008).

The types of traumatic events identified in Table 7.16 can lead to stress disorders, in part, because they challenge the basic assumptions that most people have about the world. These assumptions can be categorized into four types (Everly & Lating, 2004):

1. *The belief in a fair and just world*, where people get what they deserve and deserve what they get. When an individual who believes himself or herself to be a good person experiences a traumatic event, the person's basic beliefs about justice and fairness are called into question.
2. *The belief that it is possible to trust others and be safe.* Particularly when traumatic events are perpetrated by a known and previously liked or loved person, the victim often feels doubly betrayed or abandoned, thinking, "If I loved this person and he was able to hurt me this much, how can I trust my judgment about people?" (Janoff-Bulman, 1995).
3. *The belief that it is possible to be effective in the world.* When a traumatic event occurs, people often feel that they should have done something to prevent the event or at least somehow lessen its intensity ("If only I had . . ."). Thus, traumatic events challenge people's beliefs in their ability to protect themselves and others. People may develop a sense of learned helplessness (see Chapter 6)

Johannes Simon / AFP Live/Newscom

This is the wreckage of one of the trains blasted by a bomb in the Attocha railway station in Madrid in March 2004; more than 130 people were killed. During times of political unrest, violence, or terrorism, rates of stress disorders are likely to increase.

Table 7.16 ▶ Types of Traumatic Events**Large-scale traumatic events, with multiple victims**

- Disasters
 - Natural disasters, such as earthquakes or hurricanes
 - Human-caused disasters, such as chemical spills or nuclear accidents
- War and large-scale conflict, including police action against crowds
- Direct experience of injuring or killing others, or witnessing such events
- Mass violence against noncombatants, such as guerrilla-perpetrated atrocities and terrorist acts
- Large-scale transportation accidents, such as train derailments or airplane crashes

Unintended acts involving fewer people

- Motor vehicle accidents
- Exposure of emergency workers, such as firefighters and rescue workers, to a traumatic event
- Life-threatening illnesses, such as severe heart attack and cancer

Intended personal violence

- Rape and sexual assault (the perpetrator may or may not be known to victim)
- Physical assault (the perpetrator may or may not be known to victim)
- Violence, including sexual assault, perpetrated by a spouse or intimate partner
- Torture
- Physical stalking or cyber-stalking that causes the victim to feel threatened, intimidated, afraid, or terrorized
- Child abuse

Source: American Psychiatric Association, 2000; Briere, 2004.

and become depressed (Abramson, Metalsky, & Alloy, 1989; Bandura, 1997). In addition, when a person experiences the same traumatic event as others but suffers less physical harm or loss of property, the victim may develop *survivor guilt*, feeling guilty about faring better than others did.

4. *The sense that life has purpose and meaning.* Many people believe that life—their own lives or human existence in general—has a purpose. This belief may be spiritual or religious. Traumatic events can challenge these beliefs, leading victims to feel that their existence is pointless and meaningless (Everly & Lating, 2004).

Although certain types of traumatic events are more likely than others to lead to stress disorders, individuals differ in how they perceive the same traumatic event and how they respond to it. These differences will be based, in part, on previous experience with related events, appraisal of the stressors, and coping style. Thus, we need to consider the second component of the DSM-IV-TR definition of a traumatic event: a response of intense fear, helplessness, or horror. Unfortunately, DSM-IV-TR does not offer guidance on the degree of fear, helplessness or horror that qualifies, and given the horrific nature of a traumatic event, most people would respond with at least one of these emotions (Briere, 2004).

The stress disorders are two of only a small number of disorders in DSM-IV-TR for which the criteria *explicitly include a causal factor*—in this case, a traumatic event. However, experiencing a traumatic event is a necessary but not sufficient factor leading to a stress disorder (Everly & Lating, 2004). Let's examine posttraumatic stress disorder, and contrast it with acute stress disorder; in doing so we'll address other factors that can contribute to stress disorders.

What Is Posttraumatic Stress Disorder?

Posttraumatic stress disorder (PTSD) is diagnosed when people who have experienced a trauma persistently reexperience the traumatic event, avoid stimuli related to the event, and have symptoms of anxiety and hyperarousal; these symptoms must persist for at least a month (American Psychiatric Association, 2000). These three symptoms form the *posttrauma* criteria for PTSD, as shown in Table 7.17 (Criteria B, C, and D), and they may not emerge until months or years after the traumatic event. Table 7.18 presents other information about PTSD. Case 7.7 describes the experiences of a man with PTSD.

CASE 7.7 ► FROM THE OUTSIDE: Posttraumatic Stress Disorder

A. C. was a 42 year old single man, a recent immigrant who, one year before his appearance at the clinic, had walked into his place of work while an armed robbery was taking place. Two men armed with guns hit him over the head, threatened to kill him, tied him up and locked him in a closet with four other employees. He was released from the closet 4 hours later when another employee came in to work. The police were notified and A. C. was taken to the hospital where his head wound was sutured and he was released. For two weeks after the robbery A. C. continued to function as he had before the robbery with no increase in anxiety.

One day while waiting to meet someone on the street he was struck by the thought that he might meet his assailants again. He began to shiver, felt his heart race, felt dizzy, started to sweat and felt that he might pass out. He was brought to an emergency room, examined and released with a referral to victims' services. His anxiety increased so much that he was unable to return to work because it reminded him of the robbery. He started to have sleep difficulties, waking in the middle of the night to check the front door lock at home. He quit his job and dropped out of school due to his anxiety. He would have flashbacks of the guns that were used in the robbery and started to avoid people on the street who reminded him of the robbers. He began to feel guilty that he had entered the office while the robbery was in progress feeling that he somehow should have known what was occurring. His avoidance extended to the subway, exercising and socializing with friends.

(New York Psychiatric Institute, 2006)

A. C.'s symptoms didn't arise until 2 weeks after the robbery. If his symptoms had lasted for less than 4 weeks or if he had sought help from a mental health clinician within a month of the event, A. C. might have been diagnosed with acute stress disorder. Like PTSD, **acute stress disorder** also involves reexperiencing the traumatic event, avoiding stimuli related to the event, and exhibiting symptoms of anxiety and hyperarousal. However, unlike PTSD, the DSM-IV-TR criteria for acute stress disorder also involves symptoms of dissociation (American Psychiatric Association, 2000), namely:

- feeling emotionally detached or numb;
- feeling less aware of the environment, which some people describe as “being in a daze”;
- *derealization*, in which the perception or experience of the external world seems strange or unreal, as though seen through a pane of glass;
- *depersonalization*, in which the perception or experience of oneself (either one's body or one's mental processes) is altered to the point of feeling like an observer, seeing oneself from the outside; and
- *dissociative amnesia*, or loss of memory of important elements of the traumatic event.

Moreover, the symptoms must occur within 4 weeks of the trauma (as A. C.'s did), last no more than 4 weeks, and must cause distress or impair functioning. Approximately 80% of those with acute stress disorder have symptoms that persist for more than a month, at which point the diagnosis then changes to PTSD (Harvey & Bryant, 2002). Unlike A. C., though, most people who experience trauma do not develop PTSD (Breslau et al., 1998; Resnick et al., 1993; Shalev et al., 1998).

Posttraumatic stress disorder (PTSD)

The anxiety disorder that arises a month or more after a traumatic event and that involves a persistent reexperiencing of the event, avoiding stimuli related to the event, and symptoms of anxiety and hyperarousal that persist for at least a month.

Acute stress disorder

The anxiety disorder that arises within a month after a traumatic event and that involves reexperiencing of the event, avoiding stimuli related to the event, and symptoms of anxiety, hyperarousal, and dissociation that last for less than a month.

Table 7.17 ▶ DSM-IV-TR Diagnostic Criteria for Posttraumatic Stress Disorder

- A.** The person has been exposed to a traumatic event in which both of the following were present:
- (1) the person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others
 - (2) the person's response involved intense fear, helplessness, or horror.
- Note: In children, this may be expressed instead by disorganized or agitated behavior
- B.** The traumatic event is persistently reexperienced in one (or more) of the following ways:
- (1) recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions.
- Note: In young children, repetitive play may occur in which themes or aspects of the trauma are expressed.
- (2) recurrent distressing dreams of the event.
- Note: In children, there may be frightening dreams without recognizable content.
- (3) acting or feeling as if the traumatic event were recurring (includes a sense of reliving the experience, illusions, hallucinations, and dissociative flashback episodes, including those that occur on awakening or when intoxicated).
- Note: In young children, trauma-specific reenactment may occur.
- (4) intense psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event
 - (5) physiological reactivity on exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event
- C.** Persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness (not present before the trauma), as indicated by three (or more) of the following:
- (1) efforts to avoid thoughts, feelings, or conversations associated with the trauma
 - (2) efforts to avoid activities, places, or people that arouse recollections of the trauma
 - (3) inability to recall an important aspect of the trauma
 - (4) markedly diminished interest or participation in significant activities
 - (5) feeling of detachment or estrangement from others
 - (6) restricted range of affect (e.g., unable to have loving feelings)
 - (7) sense of a foreshortened future (e.g., does not expect to have a career, marriage, children, or a normal life span)
- D.** Persistent symptoms of increased arousal (not present before the trauma), as indicated by two (or more) of the following:
- (1) difficulty falling or staying asleep
 - (2) irritability or outbursts of anger
 - (3) difficulty concentrating
 - (4) hypervigilance
 - (5) exaggerated startle response
- E.** Duration of the disturbance (symptoms in Criteria B, C, and D) is more than 1 month.
- F.** The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Could Howard Hughes's problems have been related to an undiagnosed post-traumatic stress disorder? We don't know whether Hughes reexperienced any of his traumatic events (Criterion B), nor did he appear to have obvious avoidance symptoms related to the traumatic experiences (Criterion C): He continued flying after his last plane accident. He did have symptoms of increased arousal (Criterion D): irritability, hypervigilance, difficulty concentrating, and sleep problems, but these symptoms are better explained by his OCD and substance dependence. Thus, there is no evidence that Hughes suffered from PTSD.

Table 7.18 ▶ PTSD Facts at a Glance

Prevalence
<ul style="list-style-type: none"> Among adults in the United States, approximately 8% develop PTSD, although this number varies depending on political events.
Comorbidity
<ul style="list-style-type: none"> About 80% of those with PTSD also have another psychological disorder, most commonly a mood disorder, substance use disorder, or other anxiety disorder (Kessler et al., 1995).
Onset
<ul style="list-style-type: none"> Symptoms usually begin within 3 months of the traumatic event, although people may go months or years before symptoms appear. However, people who develop PTSD usually show symptoms in the immediate aftermath of the trauma; approximately 80% of people with acute stress disorder go on to develop PTSD (Harvey & Bryant, 2002).
Course
<ul style="list-style-type: none"> Duration of the symptoms varies. About half of those with PTSD recover within 3 months, whereas others continue to have persistent symptoms for more than a year after the traumatic event. Still others have symptoms that wax and wane.
Gender Differences
<ul style="list-style-type: none"> Women who have been exposed to trauma develop PTSD more often than do men (American Psychiatric Association, 2000; Tolin & Foa, 2006), although males are more likely to be victims of trauma (Tolin & Foa, 2006).
Cultural Differences
<ul style="list-style-type: none"> Across cultures, people with PTSD may differ in the particular symptoms they express (e.g., more intrusive symptoms versus more arousal symptoms) depending on the coping styles that are encouraged in a given culture (Marsella, Friedman, & Spain, 1996). Black Americans, who are more likely to live in high-crime neighborhoods, develop PTSD at a higher rate than do white Americans (Himle et al., in press).

Criticisms of the DSM-IV-TR Criteria for Posttraumatic Stress Disorder

The diagnosis of PTSD was introduced into the DSM in the third edition (American Psychiatric Association, 1980), thereby officially recognizing the persistent mental suffering of some trauma victims. However, the diagnosis of PTSD is controversial for several reasons:

1. The distress and suffering experienced by people months after a traumatic event are not necessarily pathological, but including of them as criteria in the DSM defines the experiences as pathological (McHugh & Triesman, 2007; McNally, 2007; Spitzer, First, & Wakefield, 2007; Summerfield, 2001).
2. Many of the symptoms of PTSD (e.g., problems concentrating and sleeping, irritability) overlap with those of depression and anxiety, and therefore the apparent symptoms of PTSD may in fact be symptoms of those other disorders (Bodkin et al., 2007; Spitzer, First, & Wakefield, 2007).
3. The original criteria for PTSD involved traumatic events far outside those normally experienced during the ordinary course of life, such as war, rape,

kidnapping, or torture. The criteria were later altered to include more common traumatic events, such as car accidents and crime victimization (Summerfield, 2001), as experienced by A. C. in Case 7.7.

4. The criteria were altered for DSM-IV so that “second-hand victimization” is possible—that is, hearing about a traumatic event qualifies as having experienced it (McNally, 2003; Spitzer, First, & Wakefield, 2007).
5. What originally started as a way to understand war-related stress symptoms among soldiers has become something else—a way to seek the status of “victim” (Summerfield, 2001) for legal, financial, or psychological reasons (Spitzer, First, & Wakefield, 2007).
6. PTSD is the only diagnosis for which people can sue for compensation (Mezey & Robbins, 2001). Critics have claimed that the existence of a financial incentive means that PTSD is overdiagnosed, and people are intentionally or inadvertently encouraged to report being more traumatized than they really are (Mezey & Robbins, 2001; Spitzer, First, & Wakefield, 2007). Support for this claim comes from surveys that have found substantially lower rates of PTSD in people outside North America (Creamer, Burgess, & McFarlane, 2001; Perkonig et al., 2000).

Taken together, these criticisms indicate that not all researchers agree with the DSM-IV-TR definition of a traumatic event or the specific diagnostic criteria for PTSD.

Understanding Posttraumatic Stress Disorder

Given that most people who experience a trauma do not go on to develop PTSD, the neuropsychosocial approach can help explain how neurological, psychological, and social factors can influence each other in particular ways and lead to PTSD. The various factors that contribute to PTSD may arise before the trauma, during the trauma, or after the trauma. Some form of combat-related stress disorder has been recognized for many decades, even centuries, giving researchers clues about possible factors to investigate more systematically.

Neurological Factors

The neurological factors that contribute to PTSD appear to arise, in large part, from interactions between the frontal lobe and the amygdala. In addition, the neurotransmitters norepinephrine and serotonin have been implicated in the disorder, and there is evidence that genes contribute to (but by no means determine) the likelihood that experiencing trauma will result in PTSD.

Brain Systems

Research has often shown that PTSD sufferers react more strongly to cues that they associate with their traumatic experience than do others. The cues can cause sweating or a racing heart (Orr, Metzger, & Pitman, 2002; Orr et al., 1993; Prins, Kaloupek, & Keane, 1995). Furthermore, the changes in heart rate are distinct from the changes found in control participants who have been asked to pretend having PTSD (Orr & Pitman, 1993). Thus, PTSD patients are not simply pretending, but do in fact react more strongly to the relevant cues than would be expected if they did not have a disorder.

In an effort to chart the mechanisms that give rise to these reactions, researchers have studied the brains of PTSD patients. First, MRI studies have shown that PTSD patients have smaller hippocampi than control participants (Bremner et al., 1995, 1997, 2003). Combat veterans with PTSD also had smaller hippocampi than other combat veterans who did not have PTSD (Gurvits et al., 1996). Second, the hippocampus apparently must work harder than normal in PTSD patients when they try to remember information, as shown by the fact that it is more strongly activated in these patients during memory tasks than in control participants (Shin et al.,

2004). The abnormal structure and function of the hippocampus in PTSD patients is important because that brain structure plays a crucial role in storing information in memory (Squire & Kandel, 2000), and thus an impaired hippocampus should impair memory. And, in fact, as expected, PTSD patients have trouble recalling autobiographical memories (McNally et al., 1995).

Note that correlation does not imply causation; perhaps the brain abnormality predisposes people to PTSD, or perhaps PTSD leads to the brain abnormality (McEwen, 2001; Pitman, Shin, & Rauch, 2001). A twin study provides an important hint about what causes what: In this study, researchers compared the sizes of the hippocampi in veterans who had served in combat and had PTSD with the sizes of hippocampi in their identical twins who had not served in combat and did not have PTSD. The results were clear: In both twins, the hippocampi were smaller than normal (Gilbertson et al., 2002). This finding implies that the trauma does not cause the hippocampus to become smaller, but rather the smaller size is a risk factor (or is correlated with some other factor that produces the risk) that makes a person vulnerable to the disorder.

Neuroimaging studies have focused not only on the hippocampus but also on the entire brain, in an effort to discover more generally which brain functions have been disrupted by PTSD (Rauch et al., 1996; Rauch, Shin & Phelps, 2006; Shin et al., 1999). For example, in some studies, researchers either show patients pictures of trauma-related stimuli (such as jungle scenes in Vietnam for Vietnam-war vets) or ask them to visualize such scenes. When PTSD patients visualize their own traumatic events, parts of the limbic system and related areas are activated, which is not surprising given the role these areas play in emotion. In addition, areas of the brain involved in visual perception are highly activated, which may indicate that these patients have particularly vivid visual mental images (Kosslyn, Thompson, & Ganis, 2006).

In addition, some studies have found that when PTSD patients see faces with fearful expressions (which can be presented so quickly that the participants aren't consciously aware of seeing them), their amygdalas become abnormally highly activated (Pitman, Shin, & Rauch 2001; Rauch, Shin, & Phelps, 2006; Rauch et al., 2000). Moreover, curiously, in three of these studies, patients with PTSD had less activation in Broca's area (in the left frontal lobe) when visualizing traumatic stimuli (Broca's area plays a key role in language production). Shin and colleagues (1997) suggest that these patients may be "scared speechless," which dampens down activity in this area. In fact, the more activated the amygdala, the less activated this area of the frontal lobe tends to be in these patients (Shin et al., 2005). It is possible that people who don't develop PTSD can use language to reinterpret trauma, and thereby lessen its impact—but PTSD patients may be overwhelmed by the sensory images, which interfere with using language in this way.

Neural Communication

Initially, researchers thought of PTSD as an extreme response to stressful situations. If so, then the brain would produce abnormal amounts of stress-related hormones, such as cortisol (Yehuda et al., 1991). But this turned out not to be the case—in fact, patients with PTSD actually have lower-than-normal levels of this hormone (Yehuda et al., 1995, 1996), even immediately after the traumatic event (McFarlane, Atchison, & Yehuda, 1997).

Even though the initial theory turned out not to be correct, it contained a grain of truth: PTSD patients do experience stress when they recall the traumatic event, and the brain does respond to stress in specific ways. In particular, when animals are forced to confront stressors, the locus coeruleus (a small structure in the brainstem) produces norepinephrine, a neurotransmitter that may be involved in PTSD (Charney et al., 1993; Southwick et al., 1994). Southwick and colleagues (1993) provided support for this theory. They gave a drug that allows norepinephrine levels to surge to volunteers with and without PTSD. When norepinephrine levels became very high, 70% of the PTSD patients had a panic attack, and 40% of them had a flashback

to the traumatic event that precipitated their disorder. Moreover, this drug resulted in more extreme biochemical and cardiovascular effects for the PTSD patients than for the controls. However, neuroimaging studies have not documented abnormal activity in the locus coeruleus when these patients are confronted with the relevant stimulus cues. One possibility is that the locus coeruleus only creates abnormal levels of norepinephrine when the person is under larger amounts of stress than are induced by the usual stimuli. Another possibility is that stress itself is another sort of trigger for panic attacks in people with PTSD, operating along with images of the relevant stimuli.

Various types of evidence indicate that serotonin also plays a role in PTSD. For one, SSRIs can help treat the disorder, and apparently do so in part by allowing serotonin to moderate the effects of stress (Corchs, Nutt, Hodd, & Bernik, 2009). In addition, people who have certain alleles of genes that produce serotonin are susceptible to developing the disorder following trauma (Adamec, Holmes, & Blundell, 2008; Grabe et al., in press). However, research has shown that the effects of such genes may depend on a combination of factors, such as stressful environmental events in combination with low social support—and the same factors that affect whether people develop PTSD also affect whether they develop major depressive disorder (Kilpatrick et al., 2007). Thus, the effects of serotonin on PTSD are likely to be complex, and perhaps arise because of how it affects more general aspects of brain function.

Genetics

Some people may have a genetic predisposition to develop PTSD (Shalev et al., 1998; True et al., 1993). However, genes appear either to play a smaller role than the environment in predicting PTSD (McLeod et al., 2001) or to be relevant only in the context of complex interactions between genes and environment (Broekman, Olff, & Boer, 2007). Consider a study of twin pairs where all twins served in the military during the Vietnam War. Results of the study found that a twin was nine times more likely to develop PTSD if he had been in heavy combat in Vietnam than if he had not been in combat. Controlling for the amount of time in combat, researchers found that genes account for about one third of the variance in PTSD symptoms (True et al., 1993). Unique environmental experiences (such as being in a fierce battle) could account for the remaining variance.

Psychological Factors: History of Trauma, Comorbidity, and Conditioning

Psychological factors that exist before the traumatic event occurs affect whether a person will develop PTSD. Such factors include a history of depression or other psychological disorders (Brewin, Andrews, & Valentine, 2000), and the beliefs the person has about himself or herself and the world. Two specific beliefs that can create a vulnerability for PTSD are considering yourself unable to control stressors (Heinrichs et al., 2005; Joseph, Williams, & Yule, 1995) and the conviction that the world is a dangerous place (Keane et al., 1985; Kushner et al., 1992).

In addition, PTSD patients who have lower IQs tend to have more severe symptoms (Kremen et al., 2007; Macklin et al., 1998; McNally & Shin, 1995). However, this finding does not imply a causal relation in either direction. IQ might lead to some other factor, which in turn is responsible for the severity of symptoms. For example, one study found that children with IQs over 115 (more than 1 standard deviation above average; see Chapter 3) were less likely to experience a traumatic event by age 17 (Breslau, Lucia, & Alvarado, 2006). It may be that people with lower IQs are less adept at avoiding traumatic events. Alternatively, perhaps they believe that they cannot control traumatic events, and that's why there is a correlation between IQ and the severity of PTSD symptoms. In fact, perceiving that you have no control over the traumatic event as it is taking place or that your life is at risk during the event (whether or not the threat is that serious) can promote PTSD (Foa, Steketee, & Rothbaum, 1989).

Among individuals who experienced a common type of traumatic event—a car accident—those who coped during the accident by dissociating were more likely to go on to develop PTSD than those who did not (Shalev et al., 1996). Other factors that increase the likelihood of PTSD's developing after a car accident are ruminating about the accident afterward, consciously trying to suppress thoughts about it, and having intrusive, unwanted thoughts and memories about it (Ehlers, Mayou, & Bryant, 1998).

Corbis/Punchstock

People can be vulnerable to developing PTSD for a variety of reasons. For example, people with severe mental disorders such as bipolar disorder (see Chapter 6) and schizophrenia (Chapter 12) are also more likely to have PTSD, perhaps as a result of childhood abuse or assaults that occurred during episodes of mental illness. However, PTSD may go undiagnosed in this population (Mueser et al., 1998; Shevlin, Dorahy, & Adamson, 2007). PTSD is also more likely to develop in those who have some other type of anxiety disorder (Copeland et al., 2007), perhaps because most anxiety disorders involve hyperarousal and hypervigilance, which may lead people to respond to traumatic events in ways that promote a stress disorder. In addition, people who experience a traumatic event after having survived a prior traumatic event (for example, having been assaulted and then, years later, living through a hurricane) may be at risk.

During the traumatic event, people who cope by dissociating (disrupting the normal processes of perception, awareness, and memory) are more likely to develop PTSD (Shalev et al., 1996).

After the traumatic event, classical conditioning and operant conditioning may help to explain the avoidance symptoms of PTSD, in the same way that it can explain such behavior in other anxiety disorders (Mowrer, 1939). In terms of classical conditioning, the traumatic stress is the unconditioned stimulus, and both internal sensations and external objects or situations can become conditioned stimuli, which in turn can come to induce powerful and aversive conditioned emotional responses (Keane, Zimering, & Caddell, 1985).

As with other anxiety disorders, the avoidant symptoms of PTSD are negatively reinforced. In addition, drugs and alcohol can temporarily alleviate symptoms; such substance use is also negatively reinforced, and explains why people with PTSD have a higher incidence of substance abuse or dependence than do people who experienced a trauma but did not go on to develop PTSD (Chilcoat & Breslau, 1998; Jacobsen, Southwick, & Kosten, 2001). In one study of National Guard members who had been to Iraq, over half of those men and women who developed PTSD also reported problem drinking (Alvarez, 2008).

Social Factors

Social factors—both before the traumatic event and afterward—also help determine whether PTSD develops. Such factors include the additional stress of lower socioeconomic status and the level of social support provided to the trauma victim.

Socioeconomic Stress

As with other stressors in life, socioeconomic factors can influence an individual's ability to cope. People who need to worry about feeding, clothing, and housing

themselves or their families have fewer emotional resources available to cope with a traumatic event and so are less likely than more fortunate individuals to weather it without developing PTSD (Mezey & Robbins, 2001).

In addition, those who are at a socioeconomic disadvantage may be more likely to experience trauma (Breslau et al., 1998; Himle et al., in press). For instance, poorer people are more likely to live in high-crime areas and so are more likely to witness crimes or become crime victims (Norris et al., 2003).

Social Support

People who receive support from others immediately after a trauma have a lower risk of developing PTSD (Kaniasty & Norris, 1992; Kaniasty, Norris & Murrell, 1990). For example, people who have experienced trauma during military service have a lower risk of developing PTSD if they have strong social support upon returning home (Jakupcak et al., 2006; King et al., 1999).

Cultural Expression of Symptoms

A person's culture can help determine which PTSD symptoms are more prominent. Cultural patterns might "teach" one coping style rather than another (Marsella et al., 1996). For example, Hurricane Paulina in Mexico and Hurricane Andrew in the United States were about equal in force, but the people who developed PTSD afterward did so in different ways (after controlling for the severity of an individual's trauma): Mexicans were more likely to have intrusive symptoms (Criterion B in Table 7.17), such as flashbacks about the hurricane and its devastation, whereas Americans were more likely to have arousal symptoms (Criterion D in Table 7.17), such as an exaggerated startle response or hypervigilance (Norris, Perilla, & Murphy, 2001). A similar finding was obtained from a study comparing Hispanic Americans to European Americans after Hurricane Andrew (Perilla, Norris, & Lavizzo, 2002).

FEEDBACK LOOPS IN ACTION:

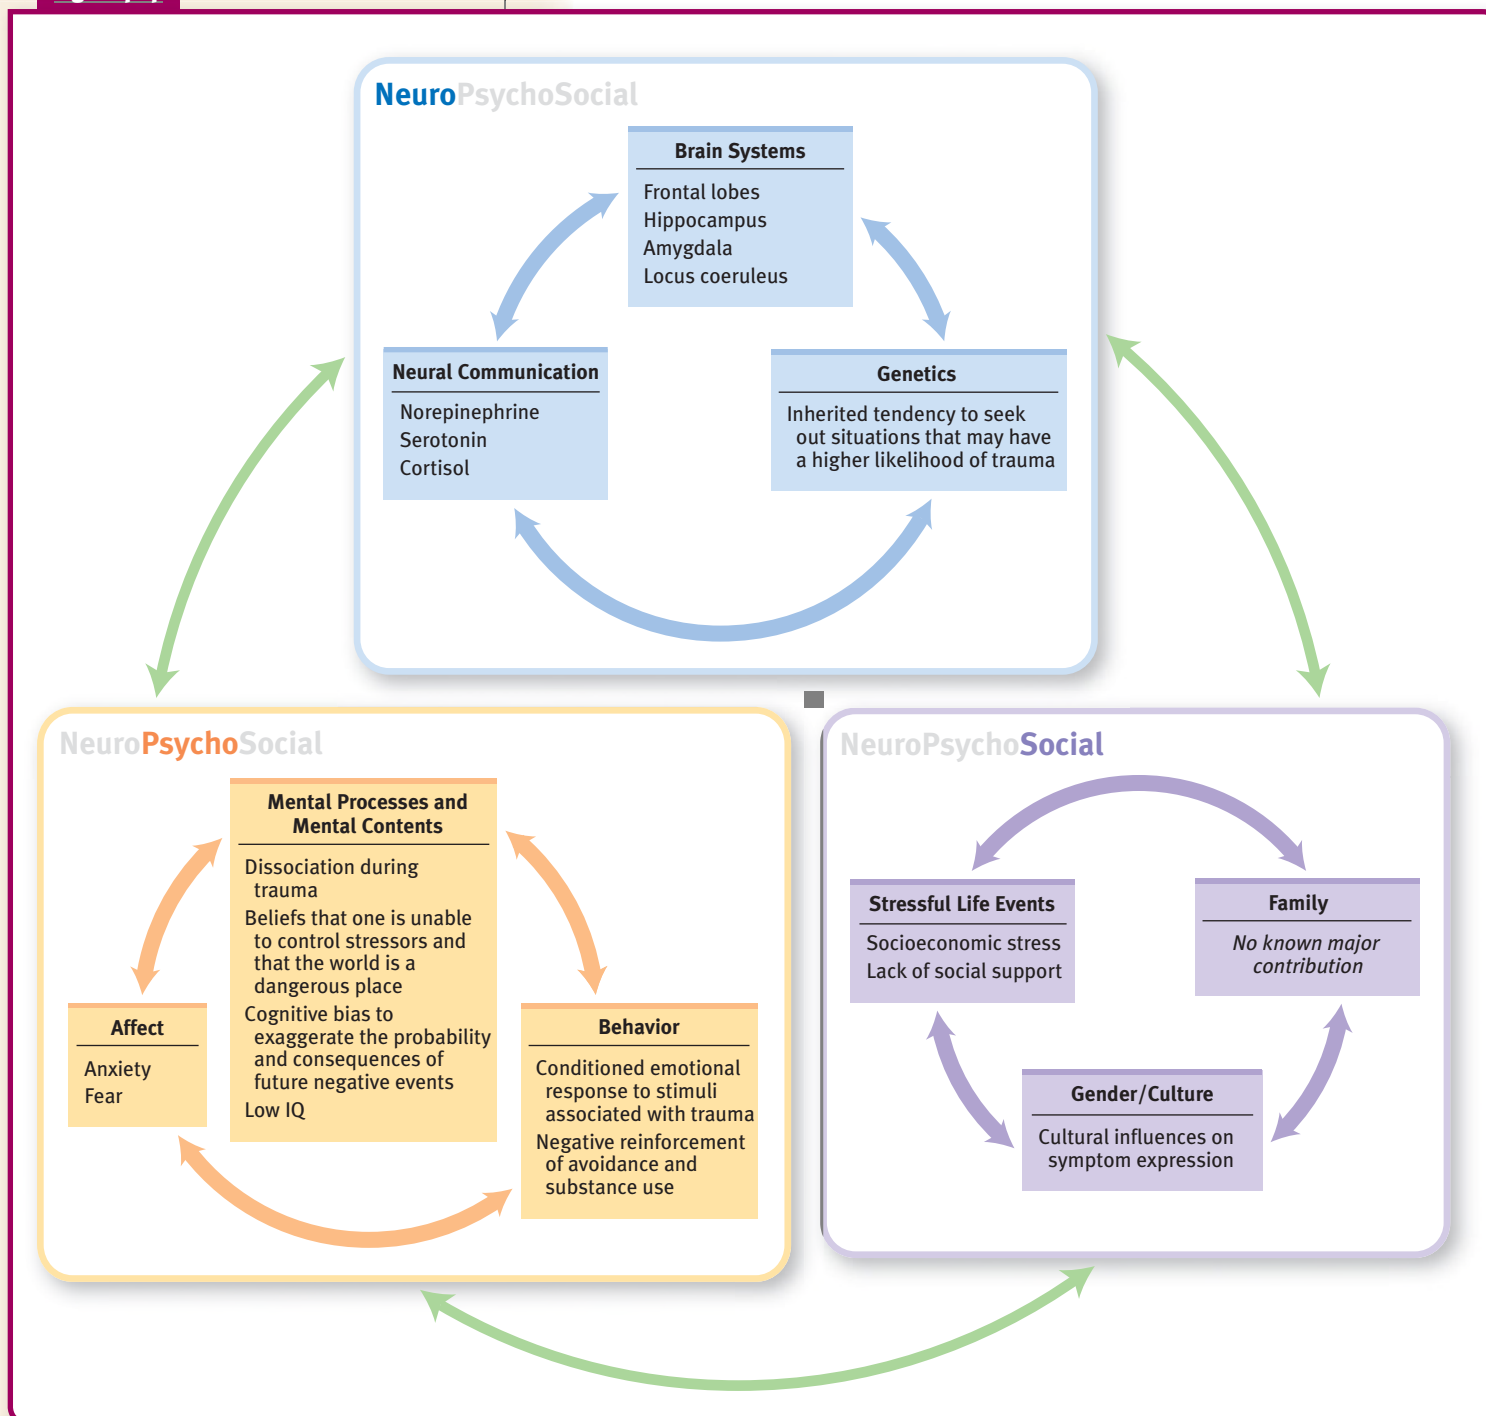

Understanding Posttraumatic Stress Disorder

Neurological, psychological, and social differences among individuals lead to their different responses to traumatic events (Bowman, 1999). Neurological factors can make some people more vulnerable to developing PTSD after a trauma. For example, in a study of those training to be firefighters, trainees who had a larger startle response to loud bursts of noise at the beginning of training were more likely to develop PTSD after a subsequent fire-related trauma (Guthrie & Bryant, 2005). In another study of male Vietnam veterans who were fraternal or identical twins, researchers found that willingness to volunteer for combat and to accept riskier assignments is partly heritable (neurological factor; Lyons et al., 1993). This heritability may involve the dimension of temperament called *novelty seeking* (see Chapter 2). Someone high in novelty seeking pursues activities that are exciting and very stimulating, and a person with this characteristic may be more likely to volunteer for risky assignments (psychological factor), increasing the chance of encountering certain kinds of trauma. This means that neurological factors can influence both psychological and social factors, which in turn can increase the risk of trauma. At the same time, when a traumatic event is more severe (social factor), other types of factors are less important in influencing the onset of PTSD (Keane & Barlow, 2002).

Furthermore, ways of viewing the world and other personality traits (psychological factors) can influence the level of social support that is available to a person after suffering trauma (social factor). Because shy people are less likely have a wide social network, they tend to have less social support than do people who seek out social activities. Even when a traumatized person has sufficient social support, if others encourage him or her to suppress thoughts of the event ("just don't think about it any more"), he or she might inadvertently increase the amount of attention paid to the traumatic experience—which increases the risk of PTSD. Figure 7.17 illustrates these factors and their feedback loops.

Figure 7.17

7.17 ► Feedback Loops in Action: Posttraumatic Stress Disorder

Treating Posttraumatic Stress Disorder

Treatments for PTSD target neurological, psychological, and social factors; as usual, when a treatment is successful, changes in one factor affect the other factors. Patients may obtain treatment that specifically targets only one type of factor or more comprehensive treatment that targets two or even all three types of factors.

Targeting Neurological Factors: Medication

The SSRIs *sertraline* (Zoloft) and *paroxetine* (Paxil) are the first-line medications for treating the symptoms of PTSD (Brady et al., 2000; Davidson et al., 1997; Stein et al., 2000). In general, an SSRI should be taken continuously for at least 9 months for fullest symptom relief (Rosenbaum et al., 2005). An added advantage of SSRIs is that these medications can also help reduce comorbid symptoms of depression (Hidalgo & Davidson, 2000)—which is important because many people with PTSD also have depression. As with other anxiety disorders, when people discontinue the medication, the symptoms may return. This is why medication is not usually the sole treatment for PTSD, but rather is combined with treatment that directly addresses psychological and social factors (Rosenbaum et al., 2005).

Two experimental treatments that directly target neurological factors hold promise for helping people with PTSD. One is the use of *propranolol* (Inderal), a beta-blocker (also used to treat performance anxiety, as noted earlier in this chapter); preliminary studies suggest that when taken soon after a traumatic event, it may decrease the risk of subsequent PTSD by diminishing neural aspects of fear conditioning (Pitman & Delahanty, 2005; Vaiva et al., 2003), although not all studies find such preventative medication treatment to be more effective than placebo (Stein et al., 2007). The other experimental treatment for PTSD is transcranial magnetic stimulation (TMS; see Chapter 4). Preliminary results suggest that TMS can reduce PTSD symptoms, but these findings need to be replicated and further understood before TMS becomes part of the repertoire of standard treatments (Cohen et al., 2004; Osuch et al., 2008).

Targeting Psychological Factors

Treatments that target psychological factors generally employ a combination of behavioral methods and cognitive methods, which, separately or in combination, are about equally effective (Keane & Barlow, 2002; Marks et al., 1998; Schnurr et al., 2007; Tarrier et al., 1999). However, most studies of CBT for acute stress disorder or PTSD do not include lengthy follow-up (Bradley et al., 2005).

U.S. Navy/Getty Images

CBT conducted online helped people who developed PTSD as a result of the September 11, 2001, terrorist attack on the Pentagon (Litz et al., 2007).

Behavioral Methods: Exposure, Relaxation, and Breathing Retraining

A traumatic experience can leave someone who has PTSD with a diminished sense of control over the environment, and perhaps over himself or herself; this person may then go to unreasonable lengths to avoid stimuli associated with the trauma. This is why treatment aims to increase a sense of control over PTSD symptoms and to decrease avoidance. Just as exposure is used to decrease avoidance associated with other anxiety disorders, it is used for PTSD: Imaginal exposure or in vivo exposure (see Chapter 4) aims to induce habituation and to reduce the avoidance of internal and external cues

Culture can help determine what kind of treatment for PTSD is appropriate. These Peruvian villagers were threatened by soldiers during a national state of emergency declared in 2003. Earlier, a study of Peruvians and Colombians exposed to traumatic experiences found that those from villages with a more individualist orientation felt that individual treatment was more appropriate, compared to those from more collectivist-oriented villages (Elsass, 2001).

Renzo Giraldo/El Comercio/AFP/Getty Images

associated with the trauma (Bryant & Harvey, 2000; Keane & Barlow, 2002). In this case, the specific stimuli in an exposure hierarchy are those associated with the trauma. As the individual becomes less aroused and fearful of these stimuli and avoids them less, mastery and control increase. To help with anxiety and reduce arousal symptoms, relaxation and breathing retraining are often included in treatment.

Cognitive Methods: Psychoeducation and Cognitive Restructuring

To diminish the difficult emotions that occur with PTSD, educating patients about the nature of their symptoms (psychoeducation) can be a first step. As patients learn about PTSD, they realize that their symptoms don't arise totally out of the blue; their experiences become more understandable and less frightening.

Cognitive methods can help patients understand the meaning of their traumatic experiences and the (mis)attributions they make about these experiences and the aftermath (Duffy, Gillespie, & Clark, 2007; Foa et al., 1991, 1999), such as "I deserved this happening to me because I should have walked down a different street."

Studies have examined whether CBT can help prevent acute stress disorder from evolving into PTSD. In fact, numerous studies have shown that CBT can significantly reduce the number of people who would have had their diagnosis change from acute stress disorder to PTSD (Bryant et al., 2005, 2006, 2008).

Targeting Social Factors: Safety, Support, and Family Education

Because the traumatic event is invariably a social stressor, the early focus of treatment is to ensure that the traumatized person is as safe as possible (Baranowsky, Gentry, & Schultz, 2005; Herman, 1992). For instance, in a case that involves domestic abuse and an ensuing stress disorder, the therapist and patient will spend time reviewing whether the woman is safe from further abuse, and if not, how to make her as safe as possible. For some types of traumatic events, such as combat-related trauma, group therapy—of any theoretical orientation—can provide support and diminish the sense of isolation, guilt, or shame about the trauma or the symptoms of PTSD (Schnurr et al., 2003). Moreover, family or couples therapy can help to educate family members and friends about PTSD and about ways in which they can support their loved one (Goff & Smith, 2005; Sherman, Zanatti, & Jones, 2005). Preliminary research suggests that interpersonal therapy (IPT; see Chapter 4), which focuses on relationship problems, may be a helpful alternative treatment for those who are not interested in CBT (Bleiberg & Markowitz, 2005).

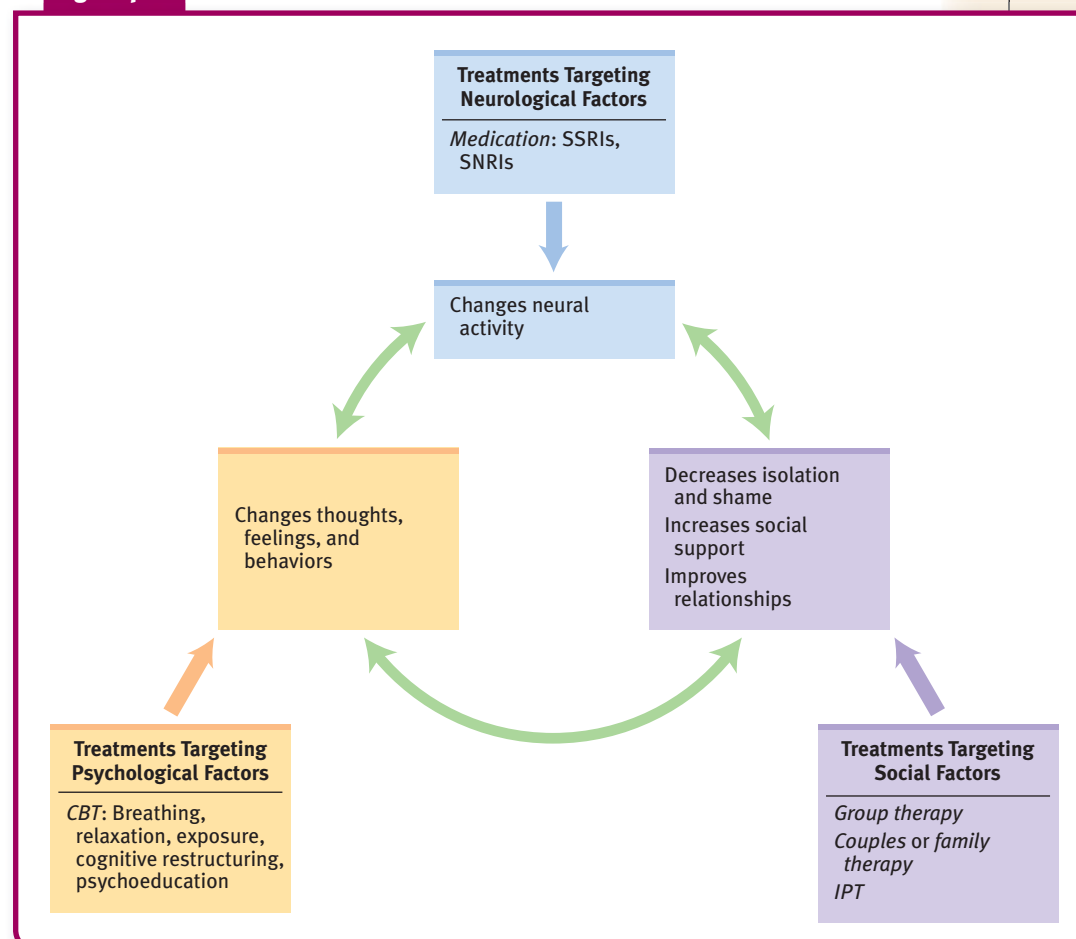

FEEDBACK LOOPS IN TREATMENT: Posttraumatic Stress Disorder

To appreciate the interactive nature of the neuropsychosocial approach, consider a study that treated people who developed PTSD after being in traffic accidents (as driver, passenger, or pedestrian) (Taylor et al., 2001). Most participants in the study had sustained injuries in the accident and had PTSD symptoms for over 2 years prior to treatment, so spontaneous remission of symptoms was unlikely. Prior to beginning the treatment, 15 of the 50 participants were taking an SSRI, a TCA, or a benzodiazepine for symptoms. Treatment consisted of 12 weeks of group CBT that involved: psychoeducation about traffic accidents, their aftereffects, and PTSD; cognitive restructuring focused on faulty thoughts (such as overrating the dangerousness of road travel); relaxation training; and imaginal and in vivo exposure.

After treatment, participants reported that they had less hyperarousal; that is, they experienced less autonomic reactivity, such as the startle response. In addition, they avoided the trauma-inducing stimuli less often and had fewer intrusive reexperiences of the trauma. These gains were maintained at the 3-month follow-up. So, an intervention that targets both social factors (group therapy with exposure to external trauma-related stimuli) and psychological factors (cognitive and

behavioral interventions to change thinking and behavior) also apparently changed neurological functioning, as indicated by the reports of decreased hyperarousal. Successful treatments for PTSD that target one or two factors ultimately affect all three. Figure 7.18 illustrates these feedback loops in treatment.

Figure 7.18

7.18 ▶ Feedback Loops in Treating Posttraumatic Stress Disorder

Key Concepts and Facts About Posttraumatic Stress Disorder

- Stress disorders are characterized by three types of persistent symptoms: reexperiencing the traumatic event avoidance of stimuli related to the event, and increased arousal and anxiety.
- DSM-IV-TR includes two types of stress disorder: acute stress disorder and posttraumatic stress disorder (PTSD). These two disorders are distinguished in part by the timing and duration of symptoms: Acute stress disorder is diagnosed when symptoms arise within 4 weeks of the stressor and have lasted for less than 4 weeks; when symptoms last more than 4 weeks the diagnosis is PTSD. The diagnostic criteria for acute stress disorder also include symptoms of dissociation.
- An event is considered traumatic if the individual experienced or witnessed an actual or threatened death or serious injury and responded with intense fear, helplessness, or horror. Types of traumatic events are large-scale events with multiple victims, unintended acts involving smaller numbers of people, and interpersonal violence. Interpersonal violence is more likely to lead to a stress disorder, as are other events in which the trauma is severe, of long duration, and of close proximity.
- The DSM-IV-TR diagnosis of PTSD has been criticized because the definition of traumatic stress is too broad, encompassing

continued on next page

normal responses to trauma, and because the symptoms specified in the criteria overlap with those for other disorders.

- Brain areas involved in PTSD include parts of the frontal lobe, the hippocampus, the locus coeruleus, and the amygdala—most of these areas are involved in emotion and fear. Patients with PTSD respond to high levels of norepinephrine by having panic attacks or flashbacks; they also have abnormal serotonin function and produce less cortisol in response to the traumatic event than do people who do not go on to develop a stress disorder. Although genes—through their influence on temperament—may affect an individual's tendency to enter risky situations, characteristics of the traumatic event itself are more important in determining whether PTSD will arise.
- Psychological factors that exist before a traumatic event contribute to PTSD; these factors include a history of depression or other psychological disorders, a belief in being unable to control stressors, the conviction that the world is a dangerous place, and lower IQ. After a traumatic event, classical and operant conditioning contribute to the avoidance symptoms.

- Social factors that contribute to PTSD include the stress of low socioeconomic status and a relative lack of social support for the trauma victim. Culture can influence the ways that individuals cope with traumatic stress.
- Medication is the treatment that directly targets neurological factors, specifically an SSRI. Treatments that target psychological factors include CBT, specifically psychoeducation, exposure, relaxation, breathing retraining, and cognitive restructuring. Treatments that target social factors are designed to ensure that the individual is as safe as possible from future trauma and to increase social support through group therapy or family therapy.

Making a Diagnosis

- Reread Case 7.7 about A. C., and determine whether or not his symptoms met the criteria for posttraumatic stress disorder. Specifically, list which apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Howard Hughes and Anxiety Disorders

We've seen that Howard Hughes may have had enough symptoms of social phobia to meet the DSM-IV-TR criteria at some points in his life, and he may have had specific phobia, other type (fear of contracting an illness). He did not seem to suffer from a stress disorder. Without a doubt, though, he clearly suffered from OCD. Although there is evidence that some of his symptoms began in childhood, his OCD symptoms worsened significantly when he was in his 40s. There are several reasons for his progressively impaired functioning at this time. First, he used increasingly larger and more frequent doses of codeine and Valium, which likely led to his diminished cognitive functioning and control over his behavior—his compulsions. Second, he had by then suffered brain damage, which came about from two sources: (1) the 14 occurrences of head trauma Hughes withstood from various plane and car accidents (Fowler, 1986), and (2) the effects of advanced syphilis (Brown & Broeske, 1996).

Hughes contracted syphilis when in his 30s, before antibiotics were available (Brown & Broeske, 1996). To treat the disease, he underwent painful and risky mercury treatment; unfortunately, the treatment was not a complete success, and by the time he was in his 40s, the disease appears to have progressed. After Hughes's death, his autopsy indicated that significant brain cell death had occurred, which is a sign of advanced syphilis (a condition previously called *general paresis*; see Chapter 1). Symptoms can include gradual personality changes and poor judgment, which may take up to 15 years to emerge. For the first few decades of his adult life, then, Hughes was able to keep his OCD symptoms sufficiently in check that his functioning was far less impaired than it became in his 50s and afterward. It is possible that the effects of syphilis and the brain trauma from his accidents exacerbated his OCD. Thus, two physical factors contributed to the worsening of Hughes's OCD symptoms: brain damage, discussed in Chapter 15, and substance abuse, which is the focus of Chapter 9.

SUMMING UP

Summary of Common Features of Anxiety Disorders

The key symptoms of anxiety disorders are extreme anxiety, intense arousal, and attempts to avoid stimuli that lead to fear and anxiety. The fight-or-flight response arises when people perceive a threat; when the arousal feels out of control—either because the individual has an overactive stress response or because he or she misinterprets the arousal—the person may experience panic. In response to the panic, some people develop a phobia of the stimuli related to their panic and anxiety symptoms.

Anxiety disorders frequently co-occur with other psychological disorders, such as depression or substance-related disorders. Mental health clinicians must determine whether the anxiety symptoms are the primary cause of the problem or are the by-product of another type of disorder. The high comorbidity of depression and anxiety disorders suggests that the two disorders share some of the same features, specifically high levels of negative emotions and distress—which can lead to concentration and sleep problems and irritability.

Thinking like a clinician

What is the difference between fear and anxiety? Why (or when) might the fight-or-flight response become a problem? If people can have symptoms of anxiety when they have other types of disorders, what determines whether an anxiety disorder is the diagnosis?

Summary of Generalized Anxiety Disorder

Generalized anxiety disorder (GAD) is marked by persistent uncontrollable worry about a number of events or activities. A majority of people with GAD also have comorbid depression. Neurological factors associated with GAD include abnormal activity of dopamine and other neurotransmitters, which influences motivation, response to reward, and attention, and a genetic predisposition to become anxious and/or depressed.

Psychological factors that contribute to GAD include being hypervigilant for possible threats, a sense that the worrying is out of control, and the reinforcing experience that worrying prevents panic. Social factors that contribute to GAD include stressful life events, which can trigger the disorder.

Treatments for GAD include (1) medication such as buspirone or an SNRI or SSRI when depression is present as a comorbid disorder; and (2) CBT, which may be employed in a group format.

Thinking like a clinician

Based on what you have read, what differentiates a “worrywart”—someone who worries a lot—from someone with GAD? If having GAD is distressing, why don’t patients simply stop worrying—what factors maintain the disorder? If someone you know with GAD asked you for advice about what kind of treatment to get, what would you recommend (based on what you have read) and why?

Summary of Panic Disorder (With and Without Agoraphobia)

The hallmark of panic disorder is recurrent panic attacks. Panic attacks may be cued by particular stimuli (usually internal sensations), or they may arise without any clear cue. Panic disorder also involves fear of further attacks and, in some cases, restricted behavior in an effort to prevent further attacks.

People in different cultures may have similar—but not identical—constellations of symptoms, such as *ataque de nervios* and wind-and-blood pressure. Some people with panic disorder also develop agoraphobia. Less commonly, people develop agoraphobia without panic disorder, but they fear triggering symptoms of panic.

Neurological factors contribute to panic disorder and agoraphobia, including: (1) A heightened sensitivity to detect breathing changes, which in turn leads to hyperventilation, panic, and a sense of needing to escape. (2) Too much norepinephrine, which increases heart and respiration rates and other aspects of the fight-or-flight response. (3) A genetic predisposition to anxiety disorders.

Psychological factors that contribute to panic disorder and agoraphobia include: (1) Conditioning of learned alarms that elicit panic symptoms. (2) Heightened anxiety sensitivity and misinterpretation of bodily symptoms of arousal in turn lead to a hypervigilance for—and fear of—further sensations, increasing arousal and creating a vicious cycle.

Social factors related to panic disorder and agoraphobia include: (1) a greater than average number of social stressors during childhood and adolescence; (2) the presence of a safe person, which can decrease

catastrophic thinking and panic; and (3) cultural factors.

The treatment that targets neurological factors is medication, specifically benzodiazepines for short-term relief and antidepressants for long-term use. CBT is the first-line treatment for panic disorder and targets psychological factors. Treatments that target social factors include group therapy focused on panic disorder and couples or family therapy, particularly when a family member is a safe person.

Thinking like a clinician

All you know about Fiona is that she has had about ten panic attacks. Is this enough information to determine whether she has panic disorder? If it is, does she have the disorder? If this isn’t enough information, what else would you want to know and why? Now suppose that Fiona starts missing Monday classes because of panic attacks on those days. She also stops going to parties on the weekend because she had a couple of panic attacks at parties. Would you change or maintain your answer about whether she has panic disorder—why or why not? Suppose Fiona does have panic disorder. Explain how she might have developed the disorder. By the end of the semester, Fiona no longer goes out of her apartment for fear of getting a panic attack. What might be appropriate treatments for Fiona?

Summary of Social Phobia (Social Anxiety Disorder)

Social phobia is an intense fear of public humiliation or embarrassment, together with an avoidance of social situations likely to cause this fear. When such social situations cannot be avoided, they trigger panic or anxiety. Social phobia may be limited to specific types of performance-related situations or may be generalized to most social situations. The anxiety about performing poorly and being evaluated by others can, in turn, impair an individual’s performance, creating a vicious cycle.

Neurological factors that give rise to social phobia include an amygdala that is more easily activated in response to social stimuli, too little dopamine in the basal ganglia, too little serotonin, and a genetic predisposition toward a shy temperament, or behavioral inhibition. Psychological factors that give rise to social phobia include cognitive distortions and hypervigilance for social threats—particularly about being (negatively) evaluated. Classical

conditioning of a fear response in social situations may contribute to social phobia; avoiding feared social situations is then negatively reinforced.

Social factors that give rise to social phobia include parents' modeling or encouraging a child to avoid anxiety-inducing social interactions. Moreover, people in different cultures may express their social fears somewhat differently.

Neurological factors are targeted by beta-blockers for periodic performance anxiety, and SSRIs or SNRIs for more generalized social phobia. The treatment that targets psychological factors is CBT, specifically, exposure and cognitive restructuring. Treatments that target social factors include group CBT and exposure to feared social stimuli.

Thinking like a clinician

Nick loved his job—he was a programmer and he worked from home. The thing he loved most about his job was that he didn't have to deal with people all day. However, his company was recently bought by a larger firm that wants Nick to start working in the central office a few days a week. His new boss tells him he'll have to attend several weekly meetings. Nick gets anxious about these changes. What determines whether Nick has a social phobia, or is just shy and nervous about the work changes? Explain your answer. If Nick gets so anxious that he can't attend the meetings, what would be an appropriate treatment for him?

Summary of Specific Phobias

Specific phobia involves excessive and irrational anxiety or fear related to a specific stimulus, and avoidance of the feared stimulus. DSM-IV-TR specifies five types of specific phobias: animal, natural environment, blood-injection-injury, situational, and other.

Neurological factors, such as an over-reactive amygdala and genetics, appear to contribute to specific phobias. Neurotransmitters involved in specific phobias include GABA, serotonin, acetylcholine, and norepinephrine. Psychological factors that give rise to specific phobias include operant conditioning, possibly classical conditioning, and cognitive biases related to the stimulus. Observational learning—a social factor—can influence what particular stimulus a person comes to fear.

The medication for specific phobia is benzodiazepines. However, medication is usually not necessary because CBT—the treatment of choice for specific phobia—is extremely effective. CBT—particularly when exposure is

part of the treatment—can work in just one session.

Thinking like a clinician

Iqbal is horribly afraid of tarantulas, refusing to enter insect houses at zoos. Do you need any more information before determining whether Iqbal has a specific phobia of tarantulas? If so—what would you need to know? If not, do you think he has a specific phobia? Explain. How might Iqbal have developed his fear of tarantulas—what factors are likely to have been involved in its emergence and maintenance? Suppose Iqbal decided that he wants to “get rid of” his fear of tarantulas. What treatments are likely to be effective and what are the advantages and disadvantages of each?

Summary of Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) is marked by persistent and intrusive preoccupations and—in most cases—repetitive behaviors that usually correspond to the obsessions. Although people with OCD recognize that their obsessions are irrational, they cannot turn off the preoccupying thoughts; they feel driven to engage in the compulsive behaviors, which provide only brief respite from the obsessions. Common obsessions include anxiety about contamination, ordering, losing control, doubts, and getting rid of objects. Common compulsions include washing, order, counting, checking, and hoarding or collecting.

Neurological factors associated with OCD include disruptions in the normal activity of a neural loop among frontal lobes, the thalamus, and the basal ganglia such that the frontal lobes do not turn off the neural loop, which may then lead to the persistent obsessions. Genes appear to make some people more vulnerable to anxiety disorders in general—not necessarily to OCD specifically.

Psychological factors that may underlie OCD include negative reinforcement of the compulsive behavior. In addition, normal preoccupying thoughts may become obsessions when the thoughts are deemed “unacceptable” and hence require controlling. In turn, the thoughts lead to anxiety, which is then relieved by a mental or behavioral ritual. Like people with other anxiety disorders, people with OCD have cognitive biases related to their feared stimuli, in this case, regarding the theme of their obsessions.

Social factors related to OCD include socially induced stress, which can influence the onset and course of the disorder, and culture,

which can influence the particular content of obsessions and compulsions.

Medication (such as an SSRI or clomipramine) is the treatment for OCD that directly targets neurological factors. The primary treatment for OCD—exposure with response prevention—directly targets psychological factors. Cognitive restructuring to reduce the irrationality and frequency of the patient's intrusive thoughts and obsessions may also be employed. Family education or therapy, targeting social factors, may be used as an additional treatment to help the patient's family function in a more normal way.

Thinking like a clinician

You visit a new friend. When you use her bathroom, you notice that all her toiletries seem very organized. Her kitchen is also neatly ordered. The next day, you notice that her classwork is well-organized—arranged neatly in color-coded folders and notebooks. You don't think twice about it until she drops her open backpack and all her stuff falls out, spilling all over the floor. She starts to cry. Based on what you have learned, do you think she has OCD? Why or why not? If she has OCD, is it because she has inherited the disorder? Explain your answer. If she does have OCD, what sorts of treatments should she consider?

Summary of Posttraumatic Stress Disorder

Stress disorders are characterized by three types of persistent symptoms: reexperiencing of the traumatic event avoidance of stimuli related to the event, and increased arousal and anxiety. DSM-IV-TR includes two types of stress disorder: acute stress disorder and posttraumatic stress disorder (PTSD). These two disorders are distinguished in part by the timing and duration of symptoms. The diagnostic criteria for acute stress disorder also include symptoms of dissociation.

An event is considered traumatic if the individual experienced or witnessed an actual or threatened death or serious injury and responded with intense fear, helplessness, or horror. Interpersonal violence is more likely to lead to a stress disorder, as are traumatic events that are severe, of long duration, and of close proximity. The DSM-IV-TR diagnosis of PTSD has been criticized because the definition of traumatic stress is too broad, encompassing normal responses to trauma, and because the symptoms specified in the criteria overlap with those of other disorders.

Brain areas involved in PTSD include parts of the frontal lobe, the hippocampus, the locus coeruleus, and the amygdala—most of these areas are involved in emotion and fear. Patients with PTSD respond unusually to high levels of norepinephrine, have disrupted serotonin function, and produce less cortisol in response to the traumatic event than do people who do not go on to develop a stress disorder.

Psychological factors that exist before a traumatic event contribute to PTSD; these factors include a history of depression or other psychological disorders, a belief in being unable to control stressors, the conviction that the world is a dangerous place, and lower IQ. After a traumatic event, classical and operant conditioning contribute to the avoidance symptoms. Social factors that contribute to PTSD include the stress of low socioeconomic status and a relative lack of social support for the trauma victim.

Medication is the treatment that directly targets neurological factors, specifically an SSRI. Treatments that target psychological factors include CBT. Treatments that target social factors are designed to ensure that the individual is as safe as possible from future trauma, and to increase social support through group therapy or family therapy.

Thinking like a clinician

Two friends, Farah and Michelle, came back from winter break. Each had been devastated by personal experiences that occurred during the break. Farah's house burned down after the boiler exploded; fortunately, everyone was safe. Michelle's house had also been destroyed in a fire, but the police believed it was set by an "enemy" of her father's. Six months pass, and by the time they go home for summer vacation, one of the friends has developed PTSD. Which friend do you think developed PTSD and why (based on what you have read)? What symptoms might she have and why? Based on what you have read, what do you think would be appropriate treatment for her?

Follow-up on Anna O.

Anna O., a well-to-do 21-year-old woman living in Austria in the late 19th century, had been caring for her ill father for weeks. Anna and her mother alternated shifts, Anna taking the night shift, staying awake by his bedside. Her father was dying of tuberculosis, and Anna also began to feel sick. Her symptoms included severe vision problems, headaches, a persistent cough, paralysis (in her neck, right arm, and both legs), lack of sensation in her elbows, and daily periods of a state of consciousness similar to sleep-walking. After her cough developed, Anna was forbidden to take care of her father. Anna was diagnosed with **hysteria**, an emotional condition marked by extreme excitability and bodily symptoms for which there is no medical explanation.

For 2 years, Anna was treated by Dr. Joseph Breuer, a Viennese neurologist. Breuer became a colleague of Sigmund Freud and told Freud about Anna and her treatment, later described in *Studies in Hysteria* (Breuer & Freud, 1895/1955). Prior to Breuer's treatment of Anna, hypnosis was often used to treat hysteria. The physician hypnotized the patient (usually a woman) and then gave her a suggestion that the symptoms would go away. However, for some unknown reason, Breuer did not give Anna any suggestions, although he did hypnotize her. Instead, he asked her about her symptoms, and over time she told him about them. Anna and Breuer often met daily for treatment, sometimes twice a day. Anna's treatment usually involved Breuer's hypnotizing her and then asking her to tell him what she remembered about the origins of her symptoms. At other times, after being hypnotized, she simply told him what was on her mind. Anna referred to this process as the "talking cure." Freud was fascinated by Breuer's account of Anna's illness and her treatment; Breuer's "talking cure" was a precursor to psychoanalysis, and Freud's thoughts about Breuer and Anna led to the beginnings of his psychoanalytic theory (Freeman, 1980; see also Chapters 1 and 4).

Anna was diagnosed with hysteria—a common diagnosis at the time—but this term is a vague label for a condition that includes a wide range of symptoms. Hysteria is not a diagnosis in DSM-IV-TR; instead, DSM-IV-TR classifies symptoms that were once considered manifestations of hysteria as part of the diagnostic criteria for two categories of disorders: dissociative disorders and somatoform disorders. The central feature of *dissociative disorders* is **dissociation**, the separation of mental processes—such as perception, memory and self-awareness—that are normally integrated. Generally, each

Hysteria

An emotional condition marked by extreme excitability and bodily symptoms for which there is no medical explanation; hysteria is not a DSM-IV-TR disorder.

Dissociation

The separation of mental processes—such as perception, memory, and self-awareness—that are normally integrated.

Anna O. was diagnosed with hysteria, which is a vague condition that is not in the DSM-IV-TR classification system. Symptoms that were seen as part of hysteria are now generally considered to be symptoms of either dissociative disorders or somatoform disorders.

Amnesia

Memory loss, which is usually temporary but, in rare cases, may be permanent.

Identity problem

A dissociative symptom in which an individual is not sure who he or she is or may assume a new identity.

Derealization

A dissociative symptom in which the external world is perceived or experienced as strange or unreal.

Depersonalization

A dissociative symptom in which the perception or experience of self—either one's body or one's mental processes—is altered to the point of feeling like an observer, as though seeing oneself from the "outside."

individual mental process is not disturbed, but their normal integrated functioning is disturbed. (With schizophrenia, in contrast, it is the mental processes themselves, such as the form or pattern of thoughts, that are disturbed; see Chapter 12.) *Somatoform disorders* are marked by persistent bodily symptoms for which there is no medically identifiable cause. In this chapter we explore dissociative and somatoform disorders—their diagnostic criteria, criticisms of those criteria, the causes of the disorders, and treatments for them.

Dissociative Disorders

Breuer reported that Anna O. was an extremely bright young woman prone to "systematic day-dreaming, which she described as her 'private theatre.'" Anna lived "through fairy tales in her imagination; but she was always on the spot when spoken to, so that no one was aware of it. She pursued this activity almost continuously while she was engaged in her household duties" (Breuer & Freud, 1895/1955, p. 22). These dissociative states, or "absences," began in earnest when Anna became too weak to care for her father, and they became more prominent after his death in April 1881. Let's examine dissociative disorders in more detail, and then consider whether Anna's symptoms would meet the criteria for any of these disorders.

Dissociative Disorders: An Overview

Dissociation may arise suddenly or gradually, and it can be brief or chronic (Steinberg, 1994, 2001). Four types of dissociative symptoms are noted in DSM-IV-TR (American Psychiatric Association, 2000; Steinberg, 1994, 2001):

- **amnesia**, or memory loss, which is usually temporary but, in rare cases, may be permanent;
- **identity problems**, in which an individual isn't sure who he or she is or may assume a new identity;
- **derealization**, in which the external world is perceived or experienced as strange or unreal, and the individual feels "detached from the environment" or as if viewing the world through "invisible filters" or "a big pane of glass" (Simeon et al., 2000); and
- **depersonalization**, in which the perception or experience of self—either one's body or one's mental processes—is altered to the point of feeling like an observer, as though seeing oneself from the "outside." Individuals experiencing depersonalization may describe it as feeling as if "under water" or "floating," "like a dead person," "as if I'm here but not here," "detached from my body," "going through the motions," "like a robot," "emotionless," in a "brain fog," or "like my mind is a blank" (Simeon et al., 2000).

Anna O. appeared to experience derealization. After her father died, she recounted "that the walls of the room seemed to be falling over" (Breuer & Freud, 1895/1955, p. 23). She also reported having trouble recognizing faces and needing to make a deliberate effort to do so: "'this person's nose is such-and-such, his hair is such-and-such, so he must be so-and-so.' All the people she saw seemed like wax figures without any connection with her" (Breuer & Freud, 1895/1955, p. 26).

Normal Versus Abnormal Dissociation

Before you start worrying about whether you might have a dissociative disorder, you may be relieved to learn that experiencing symptoms of dissociation is not necessarily abnormal; occasional dissociating is a part of everyday life (Seedat, Stein, & Forde, 2003). For instance, you may find yourself in a class, but not remember walking to the classroom. Or, on hearing bad news, you may feel detached from yourself, as if you're watching yourself from the outside.

In some cases, periods of dissociation are part of religious or cultural rituals (Boddy, 1992). Consider the phenomenon of *possession trance* observed in some societies: During a hypnotic trance, a kind of spirit is believed to assume control of

the person's body. Later, the person has amnesia for the experience. At first glance, possession trance may seem to be a psychotic experience (delusions of spirits taking over a body), but closer examination reveals that the "possessed" person doesn't exhibit any evidence of psychosis after the trance is over.

In some instances, dissociative experiences do indicate a disorder, but not necessarily a *dissociative* disorder; other psychiatric disorders can involve dissociative symptoms, such as when depersonalization or derealization occurs during a panic attack. DSM-IV-TR reserves the category of **dissociative disorders** for cases in which perception, consciousness, memory, or identity are dissociated to the point where the symptoms are pervasive, cause significant distress, and interfere with daily functioning. Research findings suggest that pathological dissociation is qualitatively different, not simply quantitatively different, from everyday types of dissociation, such as "spacing out" (Seedat, Stein, & Forde, 2003).

Only about 2% of the U.S. population reports having experienced dissociation to the extent that would be considered abnormal (Seedat, Stein, & Forde, 2003). Surveys indicate that 4–29% of individuals who have some other type of DSM-IV-TR diagnosis may also have a dissociative disorder (Coons, 1998; Foote et al., 2006; Johnson et al., 2006; Maaranen et al., 2005).

Anna's dissociative symptoms appear to have been abnormal; she had dissociations in perception, consciousness, memory, and identity:

Two entirely distinct states of consciousness were present which alternated very frequently and without warning and which became more and more differentiated in the course of the illness. In one of these states she recognized her surroundings; she was melancholy and anxious, but relatively normal. In the other state she hallucinated and was "naughty"—that is to say, she was abusive, used to throw the cushions at people, . . . tore buttons off her bedclothes and linen with those of her fingers which she could move, and so on. At this stage of her illness if something had been moved in the room or someone had entered or left it [during her other state of consciousness] she would complain of having "lost" some time and would remark upon the gap in her train of conscious thoughts.

These "absences" had already been observed before she took to her bed; she [would] stop in the middle of a sentence, repeat her last words and after a short pause go on talking. These interruptions gradually increased till they reached the dimensions that have just been described. . . . At the moments when her mind was quite clear she would complain of the profound darkness in her head, of not being able to think, . . . of having two selves, a real one and an evil one which forced her to behave badly, and so on.

(Breuer & Freud, 1895/1955, p. 24)

Anna's dissociative experiences were clearly beyond normal ones—they were pervasive and interfered with her daily functioning.

Cultural Variations in Pathological Dissociation

People in different cultures may express dissociative symptoms differently. For example, *latah*, experienced by people—mostly women—in Indonesia and Malaysia (Bartholomew, 1994), involves fleeting episodes in which the individual uses profanity and experiences amnesia and trancelike states.

Dissociative experiences have also varied across eras. Symptoms of hysteria were common among middle- and upper-class women of the Victorian era, the period in which Anna O. lived. Women of that time and social class led severely limited lives: They were expected to marry, have children, and run the home; they were allowed to pursue only a restricted range of other activities. Some researchers hypothesize that the hysterical symptoms of Victorian women like Anna who wanted a different life were one of the few means of social protest they could employ (Kimball, 2000). As we consider each type of dissociative disorder listed in DSM-IV-TR, we'll consider whether Anna's dissociative symptoms fit the contemporary diagnoses.

Types of Dissociative Disorders

DSM-IV-TR defines four types of dissociative disorders, described in the following sections: *dissociative amnesia*, *dissociative fugue*, *depersonalization disorder*,

Dissociative disorders

A category of psychological disorders in which perception, consciousness, memory, or identity are dissociated to the point where the symptoms are pervasive, cause significant distress, and interfere with daily functioning.

Dissociative amnesia

A dissociative disorder in which the sufferer has significantly impaired memory for important experiences or personal information that cannot be explained by ordinary forgetfulness.

Soldiers with dissociative amnesia may forget combat experiences that were particularly troubling or traumatic. This soldier is attending a memorial service in Iraq for three of his comrades who were killed in a convoy attack.

and *dissociative identity disorder*. People whose symptoms do not fit neatly into the criteria of one of these disorders may be diagnosed with *dissociative disorder not otherwise specified* (DDNOS). Someone who has some, but not all, of the symptoms required for a diagnosis of one of the dissociative disorders, but whose functioning is nonetheless impaired because of those symptoms, will be diagnosed with DDNOS. The prevalence rate for DDNOS approaches those for the other dissociative disorders (Lipsanen et al., 2004), which means that as many people are diagnosed with DDNOS as are diagnosed with any of the other dissociative disorders.

The relatively high prevalence of DDNOS compared to the other four dissociative disorders suggests that the criteria for these four disorders may not adequately represent the underlying phenomena. That is, the diagnostic criteria for each of the dissociative disorders may be too narrow or strict, and thus the symptoms of some patients with significant dissociation don't "fit" the criteria neatly.

Dissociative Amnesia

Anna's native language was German, but as her condition began to worsen while she was nursing her father, she started to speak only English (a language in which she was also fluent). She developed complete amnesia for speaking the German language. Let's examine why her amnesia for speaking in her native language might be considered dissociative.

What Is Dissociative Amnesia?

Dissociative amnesia is a dissociative disorder in which the sufferer has significantly impaired memory for important experiences or personal information that cannot be explained by ordinary forgetfulness (see Table 8.1). The experiences or information typically involve traumatic or stressful events, such as occasions when the patient has been violent or tried to hurt herself or himself; the amnesia can come on suddenly. For example, soon after a bloody and dangerous battlefield situation, a soldier may not be able to remember what happened. To qualify as dissociative amnesia, the memory problem cannot be explained better by another psychological disorder, a medical disorder, or substance use; as with all dissociative disorders, it must also significantly impair functioning or cause distress (American Psychiatric Association, 2000). In Anna's case, her amnesia for speaking German could not really be considered as the loss of personal information, but conceivably could be construed as the loss of an important experience and couldn't be better

explained by another disorder—and her father's illness and declining health had been extremely stressful for her. In this case—the forgotten material (how to speak German) is not directly related to the stressful event—her father's declining health. Nonetheless, her memory problems appear to be best explained as dissociative amnesia.

The memory problems in dissociative amnesia can take any of several forms:

- *Generalized amnesia*, in which the individual can't remember his or her entire life. Although common in television shows, this type of amnesia is, in fact, extremely rare.
- *Selective amnesia*, in which the individual can remember some of what happened in an otherwise forgotten period of time. For instance, a soldier may forget about a particularly traumatic battlefield skirmish, but remember what he and another person spoke about between phases of this skirmish.
- *Localized amnesia*, in which the individual has a memory gap for a specific period of time, often a period of time just prior to the stressful event, as occurred with Mrs. Y in Case 8.1.

Additional facts about dissociative amnesia are listed in Table 8.2.

Table 8.1 ▶ DSM-IV-TR Diagnostic Criteria for Dissociative Amnesia

- A.** The predominant disturbance is one or more episodes of inability to recall important personal information, usually of a traumatic or stressful nature, that is too extensive to be explained by ordinary forgetfulness.
- B.** The disturbance does not occur exclusively during the course of Dissociative Identity Disorder, Dissociative Fugue [both discussed later in this chapter], Posttraumatic Stress Disorder, Acute Stress Disorder [both in Chapter 7], or Somatization Disorder [discussed later in this chapter] and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a neurological or other general medical condition (e.g., Amnesic Disorder Due to Head Trauma [discussed in Chapter 15]).
- C.** The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

CASE 8.1 ▶ FROM THE OUTSIDE: Dissociative Amnesia

Mrs. Y, a 51-year-old married woman . . . had a two-year history of severe depressive episodes with suicidal ideation, and reported total loss of memory for 12 years of her life . . . from the age of 37 to 49. [The amnesia began at age 49 when] she had had a car accident from which she sustained a very minor injury, but no loss of consciousness [nor any] posttraumatic stress symptoms. . . . She remembered what happened in the accident, and immediately preceding it, but suddenly had total loss of memory for the previous 12 years.

Mrs. Y had no problems recalling events which had occurred since the accident. She also had good autobiographical memory for her life events up to the age of 37.

Her parents and her grown-up children had told her that the . . . 12 years were painful for her. They would not tell her why, as they thought it would distress her even more. She was not only amnesic for these reputedly painful events, [but was unable] to recognize any of the friends she had made during that time. This included her present man friend, who was the passenger in her car at the time of the accident. Her family had told Mrs. Y that this gentleman (Mr. C) had been courting her for six years prior to the accident.

(Adapted from Degun-Mather, 2002, pp. 34–35)

Some people may spontaneously remember the forgotten experiences or information, particularly if their amnesia developed in response to a traumatic event and they leave the traumatic situation behind, as when a soldier with localized amnesia in response to combat leaves the battlefield. Anna O. recovered her ability to speak German at the end of her treatment with Dr. Breuer, after she reenacted a traumatic nightmare that she’d had when at her father’s sickbed (and that marked the start of her problems).

Understanding Dissociative Amnesia

The following sections apply the neuropsychosocial approach as a framework for understanding the nature of dissociative amnesia. Unfortunately, because the disorder is so rare, not much is known about either the specific factors that give rise to it or how those factors might influence each other. In examining what is known or hypothesized about the origins of this disorder, we’ll begin with neurological factors and focus on the possible role of the hippocampus (a brain structure that is crucial for storing new information in memory) and then consider the possible role of hormones. Next, we’ll consider psychological factors, specifically the effects of traumatic events and the nature of dissociation itself. Finally, we’ll turn to social factors and explore the possible role of abuse.

Neurological Factors: Brain Trauma?

Neurological factors are clearly involved in cases of amnesia that arise following brain injury, such as that suffered in a car accident (Piper & Merskey, 2004a). However, when amnesia follows brain injury, it is not considered to be *dissociative* amnesia. Neurological factors that may contribute to dissociative amnesia are less clear-cut, as we’ll see.

Brain Systems Some researchers have suggested that dissociative amnesia may result in part from damage to the hippocampus, which is critically involved in storing new information about events in memory. These researchers assume that periods of prolonged stress affect the hippocampus so that it does not operate well when the person is highly aroused (Joseph, 1999). The arousal—which typically accompanies a traumatic event—will impair the ability to store new information about that event. Later, this process would lead to the symptoms of dissociative amnesia for that event.

However, the idea that damage to the hippocampus underlies dissociative amnesia cannot explain all cases of the disorder. Because such damage would prevent information from being stored in the first place, the subsequent amnesia would not be reversible: There would be no way to retrieve the memories later because the memories would not exist (Allen, Console, & Lewis, 1999). That is, the

Table 8.2 ▶ Dissociative Amnesia

Course
<ul style="list-style-type: none">Patients may have one or multiple episodes of amnesia.
Gender Differences
<ul style="list-style-type: none">No gender differences in the prevalence of dissociative amnesia have been reported.
Cultural Differences
<ul style="list-style-type: none">Dissociative amnesia may be a culture-related diagnosis; there are no reported cases of this disorder (due to a traumatic event by itself, in the absence of brain damage resulting from the trauma) prior to 1800 (Pope et al., 2007).
<small>Source: Unless otherwise noted, the source is American Psychiatric Association, 2000. For more information see the Permissions section.</small>

hippocampus is a critical gate-keeper of memory; without it, new information about facts cannot be stored. If damage to the hippocampus prevents new information from being stored, then such information is not available for later retrieval (even if the hippocampus itself recovers). Given that many cases of dissociative amnesia are characterized by “recovered” memories, it is not clear what brain systems would be involved.

Neural Communication How might the hippocampus get damaged, which then could lead to some cases of dissociative amnesia? Hormones could be the culprit. As discussed in Chapter 2, our adrenal glands respond to stress by producing the hormone cortisol. This hormone plays an important role in the fight-or-flight response, by allowing the body to use stored energy more efficiently; however, there are unfortunate consequences if too much cortisol is released for too long a period. Specifically, many researchers have shown in both monkeys and humans that excessive cortisol can reduce the size of the hippocampus (Bremner et al., 1995; Sapolsky, 1996, 1997).

However, as intriguing as this idea is, there is as yet no good evidence that such hippocampal damage has occurred in all patients with dissociative amnesia; further, as noted above, such damage would prevent memories from being stored, and thus reversible amnesia should not occur (but, at least in some cases, it does). Thus, it is unlikely that too much cortisol is in fact responsible for all cases of dissociative amnesia.

Psychological Factors: Disconnected Mental Processes

Researchers have focused on two theories of how cognitive disturbances—especially amnesia—arise with dissociative disorders: *dissociation theory* and *neodissociation theory*. Both theories focus on how dissociation can arise in response to traumatic experiences—specifically, how the normal processes of memory and its relation to other cognitive processes might be disrupted. Although neither theory can completely explain the phenomenon of dissociative amnesia, both offer some insight—and hence are worth considering. Let’s examine these two theories.

Dissociation Theory The earliest theory of the origins of dissociative amnesia was dubbed the *dissociation theory* (Janet, 1907). From our perspective today, the dissociation theory appears poorly named, because it is the dissociation itself that must be explained by any theory; a more descriptive name like “arousal disruption theory” would seem more appropriate. Dissociation theory posits that very strong emotions (as occur in response to a traumatic stressor) narrow the focus of attention and also disorganize cognitive processes, which prevent them from being integrated normally. According to this theory, the poorly integrated cognitive processes allow memory to be dissociated from other aspects of cognitive functioning, leading to dissociative amnesia.

However, this theory does not specify whether the dissociation somehow blocks or alters information processing or only interferes with later retrieval of the information from memory (Guralnick, Schmeidler, & Simeon, 2000). At best the theory provides only a broad explanation for dissociative amnesia; it does not outline specific mechanisms to account for the dissociation and possible later reintegration of memory.

Neodissociation Theory In contrast, *neodissociation theory* (Hilgard, 1994; Woody & Bowers, 1994) proposes that an “executive monitoring system” normally coordinates various cognitive systems, much like a chief executive officer coordinates the various departments of a large company. However, in some circumstances (such as while a person is experiencing a traumatic event) the various cognitive systems can operate independently of the executive monitoring system. When this occurs, the executive system no longer has access to the information stored or processed by the separate cognitive systems. Memory thus operates as an independent cognitive system, and an “amnesic barrier” arises between memory and the executive system. This barrier causes the information in memory to be cut off from conscious awareness—that is, dissociated.

Although aspects of both dissociation and neodissociation theories have received some support from research (Green & Lynn, 1995; Hilgard, 1994; Kirsch & Lynn, 1998), neither theory explains the specific mechanisms involved in the dissociation or reintegration of memories.

Social Factors: Indirect Effects

Many traumatic events are social in nature, such as combat and abuse. These kinds of social traumas are likely to contribute to dissociative disorders, particularly dissociative amnesia. In fact, people with a dissociative disorder report childhood physical or sexual abuse almost three times more often than do people without a dissociative disorder (Foote et al., 2006). However, some researchers point out that traumatic events can also induce anxiety, which can lead people to have dissociative symptoms. Thus, traumatic events may not *directly* cause dissociative symptoms such as amnesia; rather such events may indirectly lead to such symptoms by triggering anxiety (Cardena & Spiegel, 1993; Kihlstrom, 2001).

As noted in Table 8.2, some researchers propose that dissociative amnesia is a disorder of modern times, because there are no written accounts of its occurring before 1800 in any culture (Pope et al., 2007).

In sum, dissociative amnesia in the absence of physical trauma to the brain is extremely rare, which makes research on etiology and treatment similarly rare. Although researchers have proposed theories about why and how dissociative amnesia arises, these theories address dissociation generally; dissociative amnesia as a disorder is not well understood. These same deficiencies—a paucity of research and broad theories that do not adequately characterize the specific mechanisms—also limit our understanding of the other dissociative disorders.

Dissociative Fugue

The key features of **dissociative fugue** are sudden, unplanned travel and difficulty remembering the past. This combination can lead sufferers to be confused about who they are and sometimes to take on a new identity.

What Is Dissociative Fugue?

A person with dissociative fugue can have an episode that lasts anywhere from a few hours to weeks or even months. During a fugue state, an individual generally seems to function normally. Once the fugue state has subsided, however, the individual may not be able to remember what occurred during it (American Psychiatric Association, 2000). Table 8.3 lists the DSM-IV-TR diagnostic criteria for dissociative fugue. Table 8.4 provides more facts about this disorder, and Case 8.2 describes Joe, who had symptoms of dissociative fugue.

Table 8.3 ▶ DSM-IV-TR Diagnostic Criteria for Dissociative Fugue

- A.** The predominant disturbance is sudden, unexpected travel away from home or one's customary place of work, with inability to recall one's past.
- B.** Confusion about personal identity or assumption of a new identity (partial or complete).
- C.** The disturbance does not occur exclusively during the course of Dissociative Identity Disorder [discussed later in the chapter] and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., temporal lobe epilepsy).
- D.** The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Dissociative fugue

A dissociative disorder that involves sudden, unplanned travel and difficulty remembering the past, which can lead patients to be confused about who they are and sometimes to take on a new identity.

Table 8.4 ▶ Dissociative Fugue Facts at a Glance**Prevalence**

- This disorder is rare, occurring in approximately 0.2% of Americans. However, the prevalence may increase after widespread traumatic events such as natural disasters or wars.

Comorbidity

- People with dissociative fugue may also have a mood disorder, posttraumatic stress disorder (PTSD), or a substance-related disorder.

Onset

- The fugue state begins after a traumatic or overwhelming event, although it is not known how much time typically passes between the event and the onset of the fugue state.

Course

- Patients usually experience only a single episode, in response to high levels of stress, and recover quickly; however, some people may continue to have amnesia for events that transpired during the fugue state.
- Very little is known about the process by which people recover from dissociative fugue (Kihlstrom, 2001).

Gender Differences

- There does not appear to be any consistent gender difference in the prevalence of dissociative fugue.

Cultural Differences

- Dissociative fugue is not observed worldwide. Syndromes that are similar occur in some cultures, but these syndromes involve running or fleeing and different kinds of memory problems.

Source: Unless otherwise noted, the source is American Psychiatric Association, 2000.

Some cultures have syndromes that are similar to dissociative fugue, such as *grisi siknis*, which shares with dissociative fugue a sudden flight from home and problems with memory. This photo shows local healers of an indigenous Miskito community in Nicaragua treating people with *grisi siknis*.

CASE 8.2 ▶ FROM THE OUTSIDE: Dissociative Fugue

“Joe” went to work at his usual time [Monday morning, and on Tuesday night he] wandered into a K-Mart 150 miles from home and said, “Could you please help me? I don’t know who I am or how I got here. Would you call the police for me?”

The police took his truck keys and located his truck. They discovered his identity, took him to the emergency room, and called his hometown where his wife had reported him missing. When he returned, he did not recognize his home, his wife, or his children. . . .

He described returning to his home and his wife as a *déjà vu* experience. He felt he had seen this woman before, but he couldn’t quite place her. At work he did not recognize any of his coworkers. When he read papers that he had written, he indicated that he could understand about 10% of the material. He had some “vague recollection that it was familiar.”

(Jasper, 2003, pp. 311, 313)

Joe’s medical tests were negative, which ruled out a physical cause for his memory problems. He received treatment using hypnosis, and over time he remembered his life and the events that led up to his fugue state: He had become extremely angry at his boss and threatened to harm him physically, then ran out of the office. Apparently, the level of his anger and capacity for violence frightened Joe so much that he went into a fugue state.

An important fact about dissociative fugue, as noted in Table 8.4, is that it does not arise in all cultures. This simple observation implies a larger role for social factors than occurs for many other psychological disorders. For example, in some cultures, instead of the DSM-IV-TR diagnosis of dissociative fugue, people can develop a *running syndrome*. Although this condition has some symptoms that are similar to those of dissociative fugue, it typically involves a sudden onset of a trancelike state and dangerous behavior such as running or fleeing, which leads to exhaustion, sleep, and subsequent amnesia for the experience. Running syndromes include (American Psychiatric Association, 2000):

- *pibloktoq* among native Arctic people,
- *grisi siknis* among the Miskito of Nicaragua and Honduras, and
- *amok* in Western Pacific cultures.

These syndromes have in common with dissociative fugue part of Criterion A (Table 8.3)—unexpected travel—but the amnesia occurs after the running episode is over, so the individual doesn’t remember that it happened. In contrast, with dissociative fugue, the memory problem arises during the fugue state, and the individual can’t remember his or her past. In addition, Criteria B, C, and D for dissociative fugue do not necessarily apply to running syndromes.

Understanding Dissociative Fugue

In the following sections we describe the research findings related to dissociative fugue, focusing on the possible role of the frontal lobes, the relationship between the disorder and hypnotizability, and the role of traumatic events.

Neurological Factors

The findings from several studies suggest that frontal lobe problems may underlie dissociative fugue. In one study, Markowitsch and colleagues (1997) asked a patient with dissociative fugue and normal controls to recall aspects of their lives while their brains were being scanned. The patient's brain was not as strongly activated in the frontal and temporal regions as the control participants' brains were. Moreover, the right hemisphere was strongly activated in the control participants, but not in the patient. The right hemisphere is known to play a special role in the retrieval of autobiographical memories (Costello et al., 1998).

In another study (Glisky et al., 2004), researchers described a patient who lost not only his memory about his past but also his memory of German, which was his native language. This patient performed poorly on neuropsychological tests that assess frontal lobe function (such as the ability to organize behavior and inhibit responses). Moreover, as fMRI scans revealed, the frontal and parietal lobes of this patient were not as strongly activated as those of normal control participants when he judged whether letters formed words. The low activation in this patient's frontal lobes was particularly striking when he was asked to evaluate German words, which he claimed he could not do. In sharp contrast, when normal bilingual participants (who spoke German) were asked to pretend that they did not speak German when evaluating these words, they exhibited large amounts of activation in the frontal lobes—which shows that they worked hard to suppress their knowledge. Apparently, the patient wasn't simply pretending to have forgotten German, but actually had lost his memory.

The reduced activation in the frontal lobes of patients with dissociative fugue might be a result of high levels of stress-related hormones (Markowitsch, 1999), which could selectively affect processes that are involved in coordinating voluntary actions and mental events—including memory retrieval (Kopelman, 2002).

Psychological Factors: Related to Hypnotizability?

People who have had dissociative fugue are often more hypnotizable than the general population and may have a greater ability to dissociate (American Psychiatric Association, 2000). There are three possible implications of this relationship:

1. being more hypnotizable makes people more vulnerable to dissociative fugue after experiencing stress;
2. having experienced a fugue state, people became more hypnotizable and possibly more able to dissociate; or
3. dissociative fugue and hypnotizability are not directly related to each other; they are correlated, but their relationship is due to a third, unknown variable (for example, and purely hypothetically, a neurological condition that affects the frontal lobe).

Researchers have yet to begin to sort out the nature of this relationship, which is especially challenging because so few cases of the disorder are available to study.

Social Factors: Combat Stress

Dissociative fugue generally occurs in response to significant stressors that involve social factors, such as combat (American Psychiatric Association, 2000). That is, someone experiencing a dissociative fugue probably experienced a traumatic event beforehand. As with dissociative amnesia, the specific mechanism by which the traumatic event induces the fugue state is not clear.

To determine whether dissociative fugue is a phenomenon limited to Western cultures, one team of researchers attempted to discover whether the DSM-IV-TR definition of dissociative fugue applied to people in Uganda; in fact, it did not (van Dujil, Cardena, & de Jong, 2005). However, some symptoms of dissociative fugue

overlapped with symptoms of possession trance and of other phenomena in the local culture, such as memory problems or temporarily assuming a new identity.

In sum, like dissociative amnesia, dissociative fugue is rare and poorly understood. Although there are clues as to possible factors that contribute to the disorder, the specific roles these factors may play and how they might influence each other are not known.

Depersonalization Disorder

Like many people, you may have experienced depersonalization. This does not mean that you have depersonalization disorder. A *persistent* feeling of being detached from one's mental processes or body is the key symptom of **depersonalization disorder**. Although the primary symptom is depersonalization, people who have this disorder may also experience derealization.

What Is Depersonalization Disorder?

People afflicted with depersonalization disorder may *feel* “detached from my body” or “like a robot,” but they do not *believe* that they are truly detached or actually a robot. They still recognize reality. (In contrast, people who have a psychotic disorder may feel and believe such things; see Chapter 12.) In addition, people with depersonalization disorder may not react emotionally to events; they may feel that they don't control their behavior and are just being swept along by what is happening around them. Table 8.5 presents the DSM-IV-TR diagnostic criteria; symptoms meet the criteria for the disorder only when they occur independently of anxiety symptoms and they impair functioning or cause significant distress.

Some researchers point out that symptoms of depersonalization have much in common with symptoms of certain anxiety disorders (see Chapter 7)—a sense of being numb or detached, dizziness or faintness, and a tendency to avoid stimuli associated with increased anxiety (Hunter et al., 2003). Moreover, panic attacks can include depersonalization and derealization, and people with depersonalization disorder often have a comorbid anxiety disorder, which can make accurate diagnosis difficult. Typically, it is the comorbid anxiety symptoms, rather than the dissociative symptoms themselves, that lead individuals with depersonalization disorder to seek help. Table 8.6 provides more facts about depersonalization disorder.

Understanding Depersonalization Disorder

Researchers are beginning to chart the neurological factors that contribute to depersonalization disorder. Unfortunately, less is known about possible psychological or social factors, perhaps because the disorder is relatively rare. Let's examine what is known and how the different types of factors might influence one another.

Table 8.5 ▶ DSM-IV-TR Diagnostic Criteria for Depersonalization Disorder

- A.** Persistent or recurrent experiences of feeling detached from, and as if one is an outside observer of, one's mental processes or body (e.g., feeling like one is in a dream).
- B.** During the depersonalization experience, reality testing remains intact.
- C.** The depersonalization causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- D.** The depersonalization experience does not occur exclusively during the course of another mental disorder, such as Schizophrenia [discussed in Chapter 12], Panic Disorder [Chapter 7], Acute Stress Disorder [Chapter 7], or another Dissociative Disorder [discussed later in this chapter], and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., temporal lobe epilepsy).

Depersonalization disorder

A dissociative disorder whose primary symptom is a persistent feeling of being detached from one's mental processes or body, although people who have this disorder may also experience derealization.

Neurological Factors

As we'll see in the following sections, studies have addressed changes in brain systems and neural communication in people who have this disorder.

Brain Systems One PET study of patients with depersonalization disorder found unusual levels of activation (either too high or too low) in parts of the brain specifically involved in various phases of perception (Simeon et al., 2000). More specifically, the study found lower than normal activity in parts of the temporal lobe that are involved in visual and auditory recognition and higher than normal activity in parts of the parietal lobe, which is involved in orienting a person in space and representing the body. The researchers noted that these findings are consistent with the idea that depersonalization disorder involves dissociations in perception.

Researchers have investigated whether depersonalization disorder also involves abnormal emotional responses (Phillips & Sierra, 2003). Specifically, in one study, researchers scanned the brains of patients with this disorder and the brains of matched controls while participants viewed pictures of neutral or aversive scenes. The researchers found that the aversive stimuli produced less activation in brain regions involved in emotional reactions (specifically, disgust) in the patients than in the controls. However, the aversive pictures had the opposite effect on part of the right frontal lobe in the patients, causing it to be unusually activated; this area is involved in regulating emotion. The findings may suggest that patients with depersonalization disorder regulate their emotions more strongly than normal—which may be why they have weaker than normal emotional reactions (Phillips et al., 2001).

Other studies converge in providing evidence that depersonalization disorder arises, at least in part, from disruptions of emotional processing (Sierra et al., 2002). For example, when patients with this disorder viewed faces with highly emotional expressions, activity in the limbic system decreased—and this occurred in response to both very happy and very sad expressions (Lemche et al., 2007). This study also showed that the patients had unusually high levels of activity in the frontal lobes when viewing such facial expressions. This is important, because if the frontal lobes can suppress emotional responses, the result might be the sense of emotional detachment that such patients report. Such an effect might also explain why brain areas involved in emotion are not activated when patients with depersonalization disorder try to remember words that name emotions, whereas these brain areas are activated when normal control participants perform this task (Medford et al., 2006).

Neural Communication Patients with depersonalization disorder do not produce normal amounts of norepinephrine. In fact, the more strongly they exhibit symptoms of the disorder, the less norepinephrine they apparently produce (as measured in their urine; Simeon, Guralnick, et al., 2003). Norepinephrine is associated with activity of the autonomic nervous system, and thus this finding is consistent with the idea that these patients have blunted responses to emotion.

Table 8.6 ▶ Depersonalization Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none">The prevalence of depersonalization disorder is unknown, but thought to be extremely low.
Comorbidity
<ul style="list-style-type: none">People with depersonalization disorder may also have symptoms of anxiety (Bremner et al., 1998; Marshall et al., 2000; Segui et al., 2000). In one sample of 204 people with depersonalization disorder, almost three quarters had had an anxiety disorder (Baker et al., 2003).Other comorbid symptoms include depression, bodily concerns, and obsessive rumination.
Onset
<ul style="list-style-type: none">The average age of onset of depersonalization disorder is 16 years old.Episodes of depersonalization can be triggered by a wide range of events, including trauma, extreme stress, depression, panic, and the ingestion of a psychoactive drug such as marijuana or alcohol (Raimo et al., 1999; Simeon, Knutelska, et al., 2003).
Course
<ul style="list-style-type: none">Episodes of depersonalization can last from seconds to years.
Gender Differences
<ul style="list-style-type: none">Twice as many women as men are diagnosed with this disorder.

Psychological Factors: Cognitive Deficits

Patients with depersonalization disorder have cognitive deficits that range from problems with short-term memory to impaired spatial reasoning, but the root cause of these difficulties appears to lie with attention: These patients cannot easily focus and sustain their attention (Guralnik et al., 2000, 2007). This is consistent with neuroimaging studies that reveal decreased activity in parts of the brain that register input from the senses. However, it is not clear whether the attentional problems are a cause or an effect of the disorder: On one hand, if a person is feeling disconnected from the world, he or she would not pay normal attention to objects and events; on the other hand, if a person had such attentional problems, this could contribute to feeling disconnected from the world. Moreover, given that many patients with depersonalization disorder also have depression or an anxiety disorder (Baker et al., 2003), it is not clear whether the problems with attention are specifically related to depersonalization disorder or arise from the comorbid disorder.

Social Factors: Childhood Emotional Abuse

We noted earlier that stressful events (often social in nature) can trigger depersonalization disorder. Moreover, a particular type of social stressor—severe and chronic emotional abuse experienced during childhood—seems to play a particularly important role in triggering depersonalization disorder (Simeon et al., 2001), although it is not clear why such abuse might lead to depersonalization disorder only in some cases. Once the disorder develops, factors such as negative mood, stress, the perception of threatening social interactions, and new environments can exacerbate its symptoms (Simeon, Knuteska, et al., 2003). For instance, if Mr. E in Case 8.3 had a fight with a friend, his depersonalization symptoms would probably become worse during the fight.

CASE 8.3 ► FROM THE OUTSIDE: Depersonalization Disorder

[Mr. E] was a 29-year-old, single man, employed as a journalist, who reported a 12-year history of depersonalization disorder. He described feeling detached from the world as though he was living “inside a bubble” and found it difficult to concentrate since he felt as though his brain had been “switched off.” His body no longer felt solid and he could not feel himself walking on the ground. The world appeared two-dimensional and he reported his sense of direction and spatial awareness to be impaired. He described himself as having lost his “sense of himself” and felt that he was acting on “auto-pilot.” He also reported symptoms of depression and some symptoms of OCD, which took the form of counting and stepping on cracks in the pavement, although he did not report the latter as a problem.

Prior to the onset of his [depersonalization disorder], he experienced transient [depersonalization] symptoms when intoxicated with cannabis. At the age of 17, he started at a new school and felt very anxious and experienced [depersonalization] symptoms when not under the influence of cannabis. He described the first time this happened as “terrifying” since he felt he had “gone into another world.” He reported difficulty with breathing and believed he may have a brain tumor or that his “brain was traumatized into a state of panic.” From the age of 17 to 19, the episodes of [depersonalization] became more frequent until they became constantly present. He reports the symptoms as “enormously restricting” his life in that he felt frustrated since he has been “unable to express or enjoy myself.”

(Hunter et al., 2003, Appendix A, pp. 1462–1463)

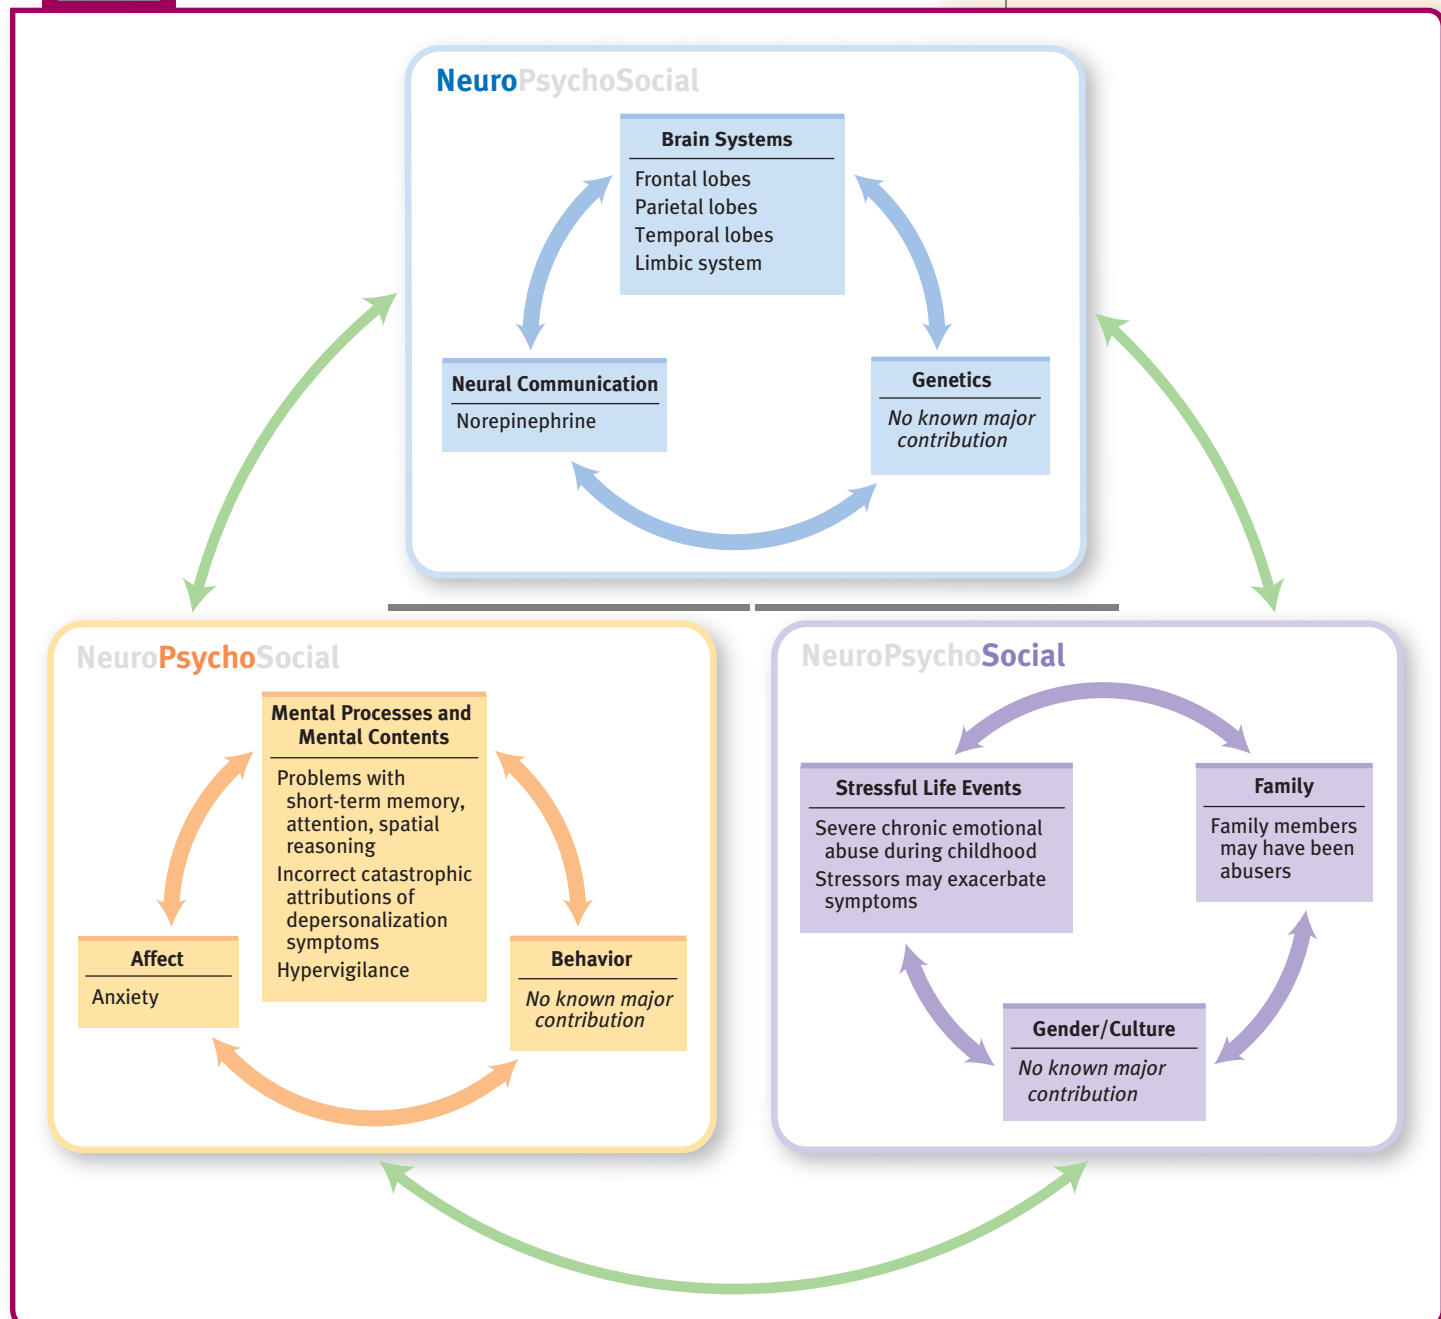

FEEDBACK LOOPS IN ACTION: Depersonalization Disorder

One hypothesis for explaining depersonalization disorder is as follows: First, a significant stressor (often a social factor) elicits neurological events (largely in the frontal lobes) that suppress the normal emotional responses (Hunter et al., 2003; Sierra & Berrios, 1998; Simeon, Knutelska, et al., 2003). Following this, the disconnection between the intensity of the perceived stress and the lack of arousal may lead these patients to feel “unreal,” which they may then attribute (a psychological factor) to being mentally ill (Baker et al., 2007; Hunter et al., 2003). And, in turn, the incorrect and catastrophic attributions that the patients make about their symptoms can lead to further anxiety (as occurs with panic disorder). The attributions

can also lead to further depersonalization or derealization symptoms. Patients then become extremely sensitive to and hypervigilant for possible symptoms of “unreality” and come to fear that the symptoms indicate that they are going “round the bend.” They may also avoid situations likely to elicit the symptoms.

Why might some people be more likely to interpret depersonalization symptoms as indicating that they are veering toward insanity? Perhaps because they had a family member with a major mental illness (social factor) (Hunter et al., 2003): When these people experience symptoms of depersonalization or derealization, rather than attributing such symptoms to external events, as normal responses to a stressor, they view the symptoms as confirming their mental illness. Figure 8.1 illustrates the three types of factors that arise in depersonalization disorder and their feedback loops.

Figure 8.1

Dissociative Identity Disorder

Dissociative identity disorder, once known as *multiple personality disorder*, may be the most controversial of all DSM-IV-TR disorders. First we examine what dissociative identity disorder is, then some criticisms of the DSM-IV-TR diagnostic criteria, and then factors that may contribute to the disorder. In the process of examining these factors, we delve into the controversy about the disorder.

What Is Dissociative Identity Disorder?

The central feature of **dissociative identity disorder (DID)** is the presence of two or more distinct *alters* (personality states or identities), each with its own characteristics and history, that take turns controlling the person's behavior. For example, a person with this disorder might have an "adult" alter that is very responsible, thoughtful and considerate and a "child" alter that is irresponsible, impulsive and obnoxious. Each alter can have its own name, mannerisms, speaking style, and vocal pitch that distinguish it from other alters. Some alters report being unaware of the existence of other alters, and thus they experience amnesia (because the memory gaps are longer than ordinary forgetting). Perhaps the most compelling characteristic

of alters is that, for a given patient, each alter can have unique medical problems and histories: One alter might have allergies, medical conditions, or even EEG patterns that the other alters do not have (American Psychiatric Association, 2000). Stressful events can precipitate a switch of alters, whereby the alter that was the dominant personality at one moment recedes and another alter becomes the dominant personality. Although the number of alters that have been reported ranges from 2 to 100, most people diagnosed with DID have 10 or fewer alters (American Psychiatric Association, 2000). Table 8.7 lists the DSM-IV-TR diagnostic criteria for DID, and Table 8.8 provides further information about the disorder. Case 8.4 presents the alters of someone with DID, which had previously been called *multiple personality disorder* (MPD).

Table 8.7 ▶ DSM-IV-TR Diagnostic Criteria for Dissociative Identity Disorder

- A.** The presence of two or more distinct identities or personality states (each with its own relatively enduring pattern of perceiving, relating to, and thinking about the environment and self).
- B.** At least two of these identities or personality states recurrently take control of the person's behavior.
- C.** Inability to recall important personal information that is too extensive to be explained by ordinary forgetfulness.
- D.** The disturbance is not due to the direct physiological effects of a substance (e.g., blackouts or chaotic behavior during alcohol intoxication) or a general medical condition. Note: In children, the symptoms are not attributable to imaginary playmates or other fantasy play.

CASE 8.4 ▶ FROM THE INSIDE: Dissociative Identity Disorder

In Robert B. Oxnam's memoir, *A Fractured Mind*, his various alters (11 in all) tell their stories. The following excerpts present recollections from two of the alters, beginning with Robert:

This is Robert speaking. Today, I'm the only personality who is strongly visible inside and outside. . . . Fifteen years ago, I rarely appeared on the outside, though I had considerable influence on the inside; back then, I was what one might call a "recessive personality."

Although [Bob, another alter] was the dominant MPD personality for thirty years, [he] did not have a clue that he was afflicted by multiple personality disorder until 1990, the very last year of his dominance. That was the fateful moment when Bob first heard that he had an "angry boy named Tommy" inside of him.

(Oxnam, 2005, p. 11)

Another alter, Bob, recounts:

There were blank spots in my memory where I could not recall anything that happened for blocks of time. Sometimes when a luncheon appointment was canceled, I would go out at noon and come back at 3 P.M. with no knowledge of where I had been or what I had done. I returned tired, a bit sweaty, but I quickly showered and got back to work. Once, on a trip to Taiwan, a whole series of meetings was canceled because of a national holiday; I had zero memory of what I did for almost three days, but I do recall that, after the blank spot disappeared, I had a severe headache and what seemed to be cigarette burns on my arm.

(Oxnam, 2005, p. 31).

Dissociative identity disorder (DID)

The dissociative disorder characterized by the presence of two or more distinct *alters* (personality states or identities), each with their own characteristics and history, that take turns controlling the person's behavior.

Criticisms of the DSM-IV-TR Criteria

Significant problems plague the DSM-IV-TR diagnostic criteria for DID, including the following (Piper & Merskey, 2004b):

- DSM-IV-TR does not define “personality states” or “identities”; accordingly, a normal emotional state that emerges episodically—such as periodic angry outbursts—could be considered an “identity.” By leaving “personality states” and “identities” undefined, the criteria allow the possibility that normal emotional fluctuations could be considered pathological.
- DSM-IV-TR does not indicate how clinicians can know when an alter has “taken control” (Criterion B) (Fahy, 1988). With no guidelines for how to make that judgment, there is apt to be little reliability in the diagnosis (see Chapter 3 for a discussion of reliability and diagnosis).
- DID—which is easy to role-play—can be difficult to distinguish from malingering (Labott & Wallach, 2002; Stafford & Lynn, 2002). When people can easily fake symptoms of a disorder, the validity of the disorder as a diagnostic entity can be questioned (see Chapter 3 for a discussion of validity and diagnosis).
- DID can be difficult to distinguish from rapid cycling bipolar disorder because both involve sudden changes in mood and demeanor. However, appropriate treatments for bipolar disorder differ from those for DID, which is why accurate diagnosis is important (Piper & Merskey, 2004b).

Some of Anna O.’s dissociative experiences seem similar to those of patients with DID, such as her “naughty” states (for which she had amnesia) and her feeling that she had two selves, a real one and an evil one, which would “take control.”

Understanding Dissociative Identity Disorder

Research findings on various factors associated with DID can be at odds with each other, which only fuels the controversy over the validity of the diagnosis itself. As we shall see, much of the research on, and theorizing about, factors that may contribute to DID hinge on the fact that many people with this disorder report having been severely and chronically abused as children (Lewis et al., 1997; Ross et al., 1991). As usual, we’ll begin by examining neurological factors and then consider psychological and social factors.

Neurological Factors: Alters in the Brain?

Research that investigates possible neurological differences between alters paints a mixed picture. On the one hand, the brain behaves differently when an alter who is aware of relevant information listens to a story than when an alter who is not aware of that information listens. As we note below, such differences in brain functioning could have something to do with early hormonal reactions to stress, and such reactions might contribute to the disorder in part because specific genes make certain people especially sensitive to stress. On the other hand, although one alter may profess to be ignorant of events experienced by other alters, rigorous testing often reveals that each alter does in fact have access to information acquired by other alters.

Brain Systems One hallmark of DID is that memories acquired by one alter are not directly accessible to other alters. However, in one study, the alters *reported* no memory for material that had been learned by other alters, but researchers nevertheless found no difference in either recall or recognition between the amnesic alters and normal control participants (Huntjens et al., 2003). Moreover, other studies suggest that although alters may report the subjective experience of amnesia, they do, in fact, have access to memories of other alters (Huntjens et al., 2005, 2006, 2007; Kong, Allen, & Glisky, 2008). Consistent with these findings, researchers have used changes in

**Table 8.8 ▶ Dissociative Identity Disorder
Facts at a Glance**

Prevalence

- The prevalence rate for DID is difficult to specify, although several surveys estimate it to be about 1% (Johnson et al., 2006; Loewenstein, 1994). However, some researchers view this figure as a significant overestimate (Rifkin et al., 1998).

Comorbidity

- People with DID may also be diagnosed with a mood disorder, a substance-related disorder, PTSD, or a personality disorder (to be discussed in Chapter 13). DID may be difficult to distinguish from schizophrenia or bipolar disorder.

Onset

- It can take years to make the diagnosis of DID from the time that symptoms first emerge. Because of this long lag time and the rarity of the disorder, there is no accurate information about the usual age of onset.

Course

- DID is usually chronic.

Gender Differences

- Although women are more likely than men to develop DID, different studies have found varying gender ratios, with women three to nine times as likely as men to receive this diagnosis.

Cultural Differences

- DID is observed only in some Western cultures and was extremely uncommon before the 1976 television movie *Sybil*, which was about a “true case” of what was then called multiple personality disorder (Kihlstrom, 2001; Lilienfeld et al., 1999).

Source: Unless otherwise noted, the source is American Psychiatric Association, 2000.

electrical activity on the scalp to show that the brain responds as if the patient with DID recognizes previously learned words, even when the learning took place when one alter was dominant and the testing occurred when another alter was dominant (Allen & Movius, 2000). For example, if an adult alter were taught the words, a child alter might claim to have no memory of them—but the brain responds to the familiar words are the same, regardless of which alter is dominant when the test is done.

However, additional research has provided evidence that patients with DID are inhibited from recalling stored information when a different alter is dominant, even if they are capable of doing so (Elzinga et al., 2003). Why might some memories be made unavailable for easy recall by particular alters? Putnam (1995) has offered a theory, which other researchers have extended to specify brain mechanisms. Specifically, the orbital frontal cortex (the lower part of the frontal lobe, behind the eyes)—which regulates many other brain regions used in various cognitive and emotional processes—may play a key role in the development of DID (Forrest, 2001). According to this theory, early abuse may prevent this area of the brain from maturing normally, and hence it is not able to integrate representations of the self normally. If memories are associated with particular representations of the self (that is, with individual alters), each representation will cue only some specific memories—which will be easier to recall than ones that are not cued by that representation.

Perhaps the key characteristic of DID is that each alter has a different “sense of self.” To the individual with DID, it feels as if different personalities “take over” in turn. To explore the neural bases of this phenomenon, Reinders and colleagues (2003) asked 11 DID patients to listen to stories about their personal traumatic history while their brains were scanned using PET. Each patient was scanned once when an alter who was aware of the past trauma was dominant and once when an alter who was not aware of the past trauma was dominant. Two results are of particular interest: First, and most basic, the brain responded differently for the two alters. This alone is evidence that something was neurologically different when the person was in the two states. Second, the traumatic history activated brain areas known to be activated by autobiographical information—but only when the alter that was aware of that information was dominant during the PET scanning. Moreover, a brain area known to process emotional information (the parietal operculum) was much more strongly activated when the participant was an alter that was aware of the trauma, compared to when the participant was an alter unaware of the trauma. Thus, from the brain’s point of view, different information was in fact accessible to the two alters.

However, it is difficult to interpret the results of many studies that investigate neurological differences among alters because the studies do not include an appropriate control group (Merckelbach, Devilly, & Rassin, 2002). Researchers have found that hypnosis can alter brain activity (Kosslyn et al., 2000), so it is possible that at least some of the neurological differences between alters reflect a form of self-hypnosis. That is, the person with DID—perhaps unconsciously—hypnotizes himself or herself, which produces different neurological states when different alters come to the fore.

Neural Communication DID is thought to be associated with early childhood abuse, and it is well known that such abuse affects a wide range of stress-related hormones, cortisol being just one. These stress-related hormones clearly disrupt brain development and subsequent brain functioning, including that of the hippocampus and the frontal lobes—both of which play major roles in memory (Teicher et al., 2002). However, researchers do not yet understand what might cause stress-related hormones to affect specifically those brain systems that in turn would produce the symptoms of the disorder.

Genetics Using a questionnaire, a team of researchers assessed the capacity for dissociative experiences in monozygotic and dizygotic twins in the general population (Jang et al., 1998). This questionnaire did not address DID directly, but it did assess the capacity for both “normal” dissociations (such as becoming very absorbed in a television show or a movie) and “abnormal” dissociations (such as not recognizing

your face in a mirror). These researchers found evidence that genetic influences account for 48% of the variance in measures of pathological dissociative experiences and 55% of the variance in measures of nonpathological experiences. In other words, almost half the variation in abnormal dissociations could be attributed to genes. Perhaps most interesting, the findings suggested that the same genetic influences underlie both sorts of dissociative experiences—which may suggest (counter to current thinking) that pathological experiences are simply an extreme on a continuum that also contains normal dissociative experiences.

Psychological Factors

The primary psychological factor associated with DID is hypnotizability—patients with this diagnosis are highly hypnotizable and can easily dissociate (Bliss, 1984; Frischholz et al., 1990, 1992). That is, they can spontaneously enter a trance state and frequently experience symptoms of dissociation, such as depersonalization or derealization. These abilities play a critical role in a psychologically based theory of DID, described in the upcoming section on feedback loops.

Social Factors: A Cultural Disorder?

Social factors have apparently affected the frequency of diagnosis of DID. From the beginning of the 20th century through the 1920s, DID was rarely diagnosed, and it continued to be rarely diagnosed until 1976 (Kihlstrom, 2001; Lilienfeld et al., 1999; Spanos, 1994). What happened in 1976? The television movie *Sybil* was aired and received widespread attention. This movie portrayed the “true story” of a woman with DID. The movie apparently affected either patients or therapists (who became more willing to make the diagnosis), or both. (Years later, it was revealed that the patient who was known as Sybil did not have alters, but rather had been encouraged by her therapist to “name” her different feelings as if they were alters; thus, what Sybil’s therapist wrote about her alters was not based on Sybil’s actual experiences [Borch-Jacobsen, 1997; Rieber, 1999].)

Consistent with the view that DID is a disorder induced by social factors present in some cultures, many countries, such as India and China, have an extremely low or zero prevalence rate of DID (Adityanjee, Raju, & Khandelwal, 1989; Draijer & Friedl, 1999; Xiao et al., 2006). In other countries, such as Uganda, people with DID symptoms are considered to be experiencing the culturally sanctioned possession trance, not suffering from DID (van Dujil, Cardeña, & de Jong, 2005).

FEEDBACK LOOPS IN ACTION: Two Models for the Emergence of Alters

Two models of dissociative identity disorder—the posttraumatic model and the sociocognitive model—are based on the existence of feedback loops among neurological, psychological, and social factors. However, the two models emphasize the roles of different factors and have different accounts of how the factors influence each other.

The Posttraumatic Model In addition to dissociating or entering hypnotic trances easily, most DID patients have at least one alter that reports having suffered severe, often recurring, physical abuse (which would imply a stress response; neurological factor) when young (Lewis et al., 1997; Ross et al., 1991). This trauma, induced by others (social factor), may increase the ease of dissociating (psychological factor), which in turn produces DID. In fact, children who experienced severe physical abuse later report that during the traumatic events their minds temporarily left their bodies as a way of coping; that is, they dissociated. Putting these observations together, the *posttraumatic model* (Gleaves, 1996) proposes that after frequent episodes of abuse with accompanying dissociation, the child’s dissociated state can develop its own memories, identity, and way of interacting with the world, thus becoming an “alter” (Putnam, 1989).

Several studies support some aspects of the posttraumatic model. As would be expected from this model, some people with DID do have documented histories of severe physical abuse in childhood (Lewis et al., 1997; Putnam, 1989; Swica,

Courtesy Everett Collection

Some researchers attribute the increased prevalence of dissociative identity disorder since 1976 to the movie *Sybil*, based on the book of the same name, which claimed to portray the “true story” of a woman with DID. In a scene near the end of the movie, Sybil (played by Sally Field, lying down) and her psychiatrist (Joanne Woodward) work to “integrate” the different alters. In fact, it was later revealed that the real life “Sybil” had been explicitly encouraged to give names to different aspects of her personality, but did not actually dissociate, as her psychiatrist had declared she did.

Lewis, & Lewis, 1996) and also report having displayed signs of dissociation in childhood (Lewis et al., 1997). Moreover these patients report that they either don't remember being abused or remember very little of it (Lewis et al., 1997; Swica, Lewis, & Lewis, 1996). In addition, girls who were easy to hypnotize *and* able to dissociate readily were found to be the ones most likely to have been abused physically or sexually (Putnam et al., 1995).

However, if the posttraumatic model is correct, there should be a significant number of cases of childhood DID. In fact, very few such cases have been documented, and most studies of abused children have found only a great ability to dissociate, *not the presence of alters* (Piper & Merskey, 2004a). Moreover, most studies of adults with DID who experienced childhood abuse have not obtained independent corroborating evidence of abuse or trauma but rather rely solely on the patient's—or an alter's—report of abuse during childhood (Piper & Merskey, 2004a, 2000b). As we saw in Chapter 5, self-reports are subject to various cognitive biases. In short, mental health professionals are divided over whether childhood trauma is the root cause of DID (Dell, 1988; Pope et al., 1999).

The Sociocognitive Model In contrast to the posttraumatic model of DID, the *sociocognitive model* proposes that social interactions between therapist and patient (social factor) foster DID by influencing the beliefs and expectations of the patient (psychological factor). According to the sociocognitive model, the therapist unintentionally causes the patient to act in ways that are consistent with the symptoms of DID (Lilienfeld et al., 1999; Sarbin, 1995; Spanos, 1994). This explanation is plausible in part because hypnosis was commonly used to bring forth alters, and researchers have pointed out that suggestible patients can unconsciously develop alters (and ensuing neurological changes) in response to the therapist's promptings (Spanos, 1994). For instance, a therapist may encourage a patient to develop alters by asking specific questions (“Have people come up to you who seem to know you, but they are strangers to you?” or “Do you find clothes in your closet that you don't remember purchasing?”) and then showing special interest when the patient answers “yes” to any such question. One finding that supports the sociocognitive model is that many people who have been diagnosed with DID had no notion of the existence of any alters before they entered therapy (Lilienfeld et al., 1999). In addition, cultural cues regarding DID (such as in portrayals in movies and memoirs or interviews of people with the disorder) may influence a patient's behavior.

The Debate About Dissociative Identity Disorder

After years of debate, the central issue regarding DID is not whether it exists, but rather how it arises and continues (McHugh, 1993). Is DID a natural response to severe and chronic childhood abuse, or is it mainly a product of influences from the

Dissociative identity disorder is described or portrayed in various films and memoirs; the photo shown here is a publicity shot for one of the earliest and best-known films, *The Three Faces of Eve*. According to the sociocognitive model of this disorder, such media portrayals can help create expectations in both patients and therapists about how people with the disorder behave. Therapists, in turn, unintentionally reinforce patients for behaving in ways consistent with such portrayals.

20thCentFox/Courtesy Everett Collection

media, the therapist, and general social expectations (Lilienfeld et al., 1999)? Proponents of the sociocognitive model recognize that childhood trauma can—at least in some cases—indirectly be associated with DID: it is possible that childhood trauma can lead people to become more suggestible or more able to fantasize, which can magnify the effects on their behavior of social interactions with a therapist (Lilienfeld et al., 1999). In other words, dissociation and DID symptoms may be *indirect* results of childhood trauma rather than direct posttraumatic results.

Proponents of the sociocognitive model point out that cultural influences, such as the airing of the movie *Sybil*, may have led therapists to ask leading questions regarding DID—and may have led highly suggestible patients to follow these leads unconsciously; such influences would account for the great variability in the number of cases over time. Proponents of the posttraumatic model counter that the increased prevalence of DID after 1976 simply reflects improved procedures for assessment and diagnosis. In support of their position, they point to the results of a study that is consistent with their model and contradicts the sociocognitive model: Women who reported having *recovered memories* (i.e., knowledge of prior events about which they previously had no memory) of childhood sexual abuse were *less* suggestible than women in a control group, not more suggestible, as would be predicted by the sociocognitive model (Leavitt, 1997). However, this study's support for the posttraumatic model isn't as strong as it might seem at first blush. Participants in the study were not DID patients, and so there may be some important difference between those who recover memories of childhood abuse and *don't* develop DID versus those who do go on to develop DID.

In sum, we do know that severe trauma can lead to dissociative disorders and can have other adverse effects (Putnam, 1989; Putnam et al., 1995). However, we do not know whether all of those who are diagnosed with DID have actually experienced traumatic events, nor even how severe an event must be in order to be considered “traumatic.” Similarly, experiencing a traumatic event does not *specifically* cause DID (Kihlstrom, 2005); some people respond by developing depression or an anxiety disorder. Further, as noted in Chapter 7, many people who experience a traumatic event do not develop any psychological disorder.

Treating Dissociative Disorders

In general, dissociative disorders improve spontaneously, without treatment. This is especially true of dissociative amnesia and dissociative fugue. However, clinicians who encounter people with these disorders have used some of the treatments discussed below. Because dissociative disorders are so rare, few systematic studies of treatments have been conducted—and none have attempted to determine which treatments are most effective for a particular dissociative disorder. Thus, we consider treatments for dissociative disorders in general.

Targeting Neurological Factors: Medication

In general, medication is not used to treat the symptoms of dissociative disorders because research suggests that it is not helpful for dissociative symptoms (Sierra et al., 2003; Simeon, Stein, & Hollander, 1998). However, people with DID may receive medication for a comorbid disorders or for anxiety or mood symptoms that arise in response to the dissociative symptoms.

Targeting Psychological and Social Factors: Coping and Integration

Treatments that target the psychological factors underlying dissociative disorders focus on three elements: (1) reinterpreting the symptoms so that they don't create stress or lead the patient to avoid certain situations; (2) learning additional coping strategies to manage stress (Hunter et al., 2005); and (3) for DID patients, addressing the presence of alters and dissociated aspects of their memories or identities. The first two foci are similar to those for treating PTSD (Kluft, 1999; see Chapter 7).

Ramin Talei/Corbis

Simply being sensitive to context or responding differently when in different emotional states does not mean that you have alters. For example, one study found that people who are bilingual responded differently to a personality test, depending on which language was used for the test (Ramírez-Esparza et al., 2006). Can you think of reasons for this result that do not involve alters?

When using hypnosis to treat dissociative symptoms, the therapist may make suggestions such as “You will feel yourself becoming relaxed . . . you will notice yourself going into a state of trance . . . you will find yourself about to remember whatever was dissociated.” One goal is to help re-integrate whatever has been dissociated, such as specific memories.

Will & Deni McIntyre/Photo Researchers, Inc.

When addressing the presence of alters in those with DID, the type of treatment a clinician employs depends on which theory he or she accepts and thus guides treatment. Proponents of the posttraumatic model advise clinicians to identify in detail (or to “map”) each alter’s personality, recover memories of possible abuse, and then help the patient to integrate the different alters (Chu et al., 2005). In contrast, proponents of the sociocognitive model advise *against* mapping alters or trying to recover possible memories of abuse (Gee, Allen, & Powell, 2003). Instead, they recommend that the therapist use learning principles to extinguish patients’ mention of alters: Alters are to be ignored, and the therapist doesn’t discuss multiple identities. Alters are interpreted as creations inspired by the patient’s desire for attention, and treatment focuses on current problems rather than on past traumas (Fahy, Abas, & Brown, 1989; McHugh, 1993).

In addition, hypnosis has sometimes been used as part of treatment, particularly by therapists who treat DID according to the posttraumatic model; in this case, hypnosis might be used to help the patient learn about his or her different alters and integrate them into a single, functional whole (Boyd, 1997; Kluft, 1999).

Using hypnosis is, by its very nature, a social event: The therapist helps the patient achieve a hypnotic state through suggestions and bears witness to whatever the patient shares about the dissociated experience. However, using hypnosis to treat DID is controversial because the patient will probably be more suggestible when in a hypnotic trance, and the therapist may inadvertently make statements that the patient interprets as suggestions to produce more DID symptoms. Fur-

ther, it is not clear that hypnosis can always help such patients, although there is some evidence that it sometimes might be useful (Powell & Gee, 1999).

Treatment may also focus on reducing the traumatic stress that can induce dissociative disorders. For instance, soldiers who experience dissociation during combat may be removed from the battlefield, which can then reduce the dissociation.

FEEDBACK LOOPS IN TREATMENT: Dissociative Disorders

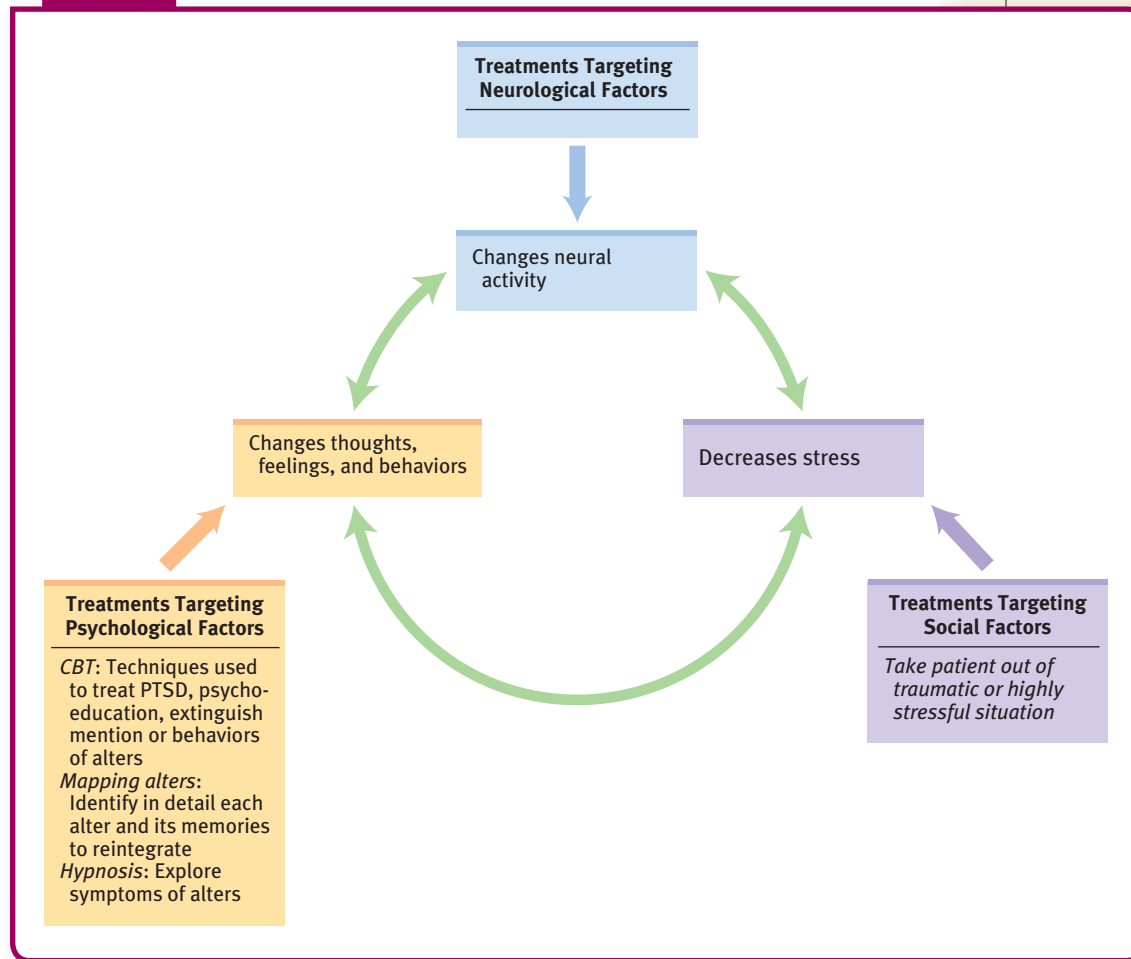

When Breuer was treating Anna O., he relied on the “talking cure”—having her talk about relevant material, at first while in a hypnotic trance and later while not in a trance. This use of hypnosis continues today, and is often part of a treatment program for people with dissociative disorders (Butler et al., 1996), including dissociative amnesia (such as Mrs. Y in Case 8.1), dissociative fugue (such as Joe in Case 8.2), and DID (Putnam & Loewenstein, 1993). Hypnotic treatment for a dissociative disorder usually involves helping the individual to become aware of and integrate dissociated perceptions and memories, as well as to understand what may have led to the dissociation. Let’s examine hypnotic treatment and how it leads to feedback loops among neurological, psychological, and social factors.

In the 1980s, researchers began to investigate the neurological changes that occur as a result of hypnosis and subsequently established that hypnosis alters brain events (Crawford et al., 1993; Kosslyn et al., 2000; Sabourin et al., 1990–1991; Spiegel, Bierre, & Rootenberg, 1989; Spiegel et al., 1985). The specific brain changes vary, however, depending on the task being performed during the hypnotic trance. When hypnotized, patients may be able to retrieve information that was previously dissociated; in turn, this may make them feel more like themselves and experience perceptions or memories in a more normal way (psychological factor).

In addition, hypnosis can be induced only when patients are willing to be hypnotized, and its beneficial effects occur when they go along with the therapist's hypnotic suggestions (social factor). In turn, the hypnotic state brings about changes in brain activity (neurological factor), which ultimately might play a role in integrating the stored information that was previously dissociated.

Figure 8.2 is a graphic representation of the three types of factors and their feedback loops in treating dissociative disorders.

Figure 8.2

8.2 ▶ Feedback Loops in Treating Dissociative Disorders

Key Concepts and Facts About Dissociative Disorders

- Dissociation involves a separation of mental processes that are normally integrated—a dissociation of perception, consciousness, memory, or identity. To qualify as a dissociative disorder, this separation must cause significant distress or impair functioning. Specific symptoms of dissociative disorders include amnesia, identity problems, derealization, and depersonalization. Dissociative disorders are rare and are often thought to arise in response to traumatic events.
- Dissociative amnesia is characterized by significantly impaired memory for important experiences or personal information that cannot be explained as ordinary forgetfulness or accounted for by another psychological disorder, substance use, or a medical condition. Dissociative amnesia most often occurs after some traumatic event. The amnesia may be generalized, selective, or localized. The amnesia may spontaneously disappear, particularly after the person leaves the traumatic situation.

continued on next page

- Dissociative fugue is characterized by sudden, unplanned travel and difficulty remembering the past, which in turn leads to identity confusion. Apparently, the frontal lobes of patients with this disorder are not as effective at accessing stored memories, particularly about the self; the reduced activation in the frontal lobes might be caused by stress-related hormones. People who have had this disorder are more hypnotizable and dissociate more easily than do others. Moreover, dissociative fugue typically occurs in response to a traumatic event.
- Depersonalization disorder is characterized by the persistent feeling of being detached from oneself, which may be accompanied by derealization. This disorder appears to involve an under-reaction to emotional stimuli, and is more common among people who experienced severe chronic emotional abuse during childhood than among people who did not have this experience.
- Dissociative identity disorder (DID) hinges on the presence of two or more distinct alters, each of which takes turns controlling the person's behavior. The DSM-IV-TR diagnostic criteria for DID have been criticized for being vague, and the symptoms are easy to fake.
- Although neuroimaging studies of patients with DID find that their brains function differently when different alters are dominant, such studies generally have not used appropriate control groups (such as one in which participants are asked to fake having this disorder). People with this disorder are more hypnotizable and dissociate more readily than do people who do not have this disorder. After the airing of the television movie *Sybil*, in 1976, the prevalence of DID increased dramatically. The diagnosis of DID is controversial.
- The posttraumatic model proposes that DID is caused by severe, chronic physical abuse during childhood, which leads to dissociation during the abuse; the dissociated states come to constitute alters, with their own memories and personality traits. The sociocognitive model proposes that DID arises as the result of interactions between a therapist and a suggestible patient, in which the therapist inadvertently encourages the patient to behave in ways consistent with the diagnosis. Both interpretations

are consistent with the finding that severe childhood trauma is associated with the disorder.

- The goal of treatment for dissociative disorders ultimately is to reduce the symptoms themselves and lower the stress they induce. For patients with DID, the specific methods employed depend on what the clinician views as the cause of the disorder: According to the posttraumatic model, therapists should help patients, perhaps through hypnosis, to characterize each alter in detail. In contrast, according to the sociocognitive model, therapists should try to extinguish patients' behaviors related to alters.

Making a Diagnosis

- Reread Case 8.1 about Mrs. Y, and determine whether or not her symptoms meet the criteria for dissociative amnesia. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 8.2 about Joe, and determine whether or not his symptoms meet the criteria for dissociative fugue. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 8.3 about Mr. E, and determine whether or not his symptoms meet the criteria for depersonalization disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 8.4 about Robert Oxnam, and determine whether or not his symptoms meet the criteria for dissociative identity disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Somatoform Disorders

During the course of her illness, Anna O. developed medical symptoms that her doctors could not explain. For instance, she saw an eye doctor for problems with her vision, but he was unable to identify the cause (Breuer & Freud, 1895/1955). Similarly, doctors were unable to find a medical explanation for her cough. How might persistent medically unexplained physical symptoms such as these arise? How should they best be treated? Such bodily symptoms may fall under the category of *somatoform disorders* in DSM-IV-TR.

Somatoform Disorders: An Overview

The hallmark of **somatoform disorders** is complaints about physical well-being that cannot be entirely explained by a medical condition, substance use, or another psychological disorder. For example, one somatoform disorder is *hypochondriasis*, which is characterized by an individual’s preoccupying belief that he or she has a serious illness, despite negative medical tests. By their very nature, however, somatoform disorders are “rule out” diagnoses, meaning that the clinician must make sure that there aren’t medical conditions or other psychological disorders that can better explain the patients’ physical symptoms. For instance, if a person repeatedly has panic attacks and complains of a racing heart, chest pain, and shortness of breath, he or she will not be considered to have a somatoform disorder, because the symptoms are explained by another psychological disorder—panic disorder.

In the absence of a medical condition or another psychological disorder, clinicians must judge the extent to which patients’ physical symptoms (see Table 8.9) impair functioning, lead to significant distress, and are not under voluntary control, and decide whether the symptoms qualify as a somatoform disorder according to DSM-IV-TR criteria. Somatoform disorders are relatively rare in the general population but are the most common type of psychological disorder in medical settings (Bass, Peveler, & House, 2001): A third of patients visiting their primary care physician have symptoms that are not adequately explained by a medical condition (Kroenke, 2003). The medical costs of caring for patients with somatoform disorders are substantial; according to one estimate, patients with these disorders account for over \$250 billion in medical costs each year (Barsky, Orav, & Bates, 2005).

Somatoform disorders are not a new phenomenon; they have a long history, although different labels have been given to them over time. They were described by the ancient Greek philosopher Hippocrates, who thought that somatoform symptoms—generally reported by women—were caused by a wandering uterus, from which the term *hysteria* is derived (*hystera* is Greek for “uterus”; Phillips, 2001). *Hysteria* was often used to refer to bodily symptoms that lack a medical explanation, as was true of Anna O.; in addition, patients with hysteria typically describe their symptoms dramatically.

Somatoform disorders must be distinguished from *factitious disorder*, mentioned in Chapter 3, in which people *intentionally* induce symptoms or falsely report symptoms that they do not in fact have to receive attention from others. Those with a somatoform disorder neither pretend to have symptoms nor intentionally induce physical symptoms for any type of gain.

Somatoform disorders share two common features (Looper & Kirmayer, 2002):

- 1. *bodily preoccupation*, which is similar to the heightened awareness of panic-related bodily sensations experienced by people with panic disorder (see Chapter 7), except that with somatoform disorders the patient can be preoccupied with any aspect of bodily functioning; and
- 2. *symptom amplification*, or directing attention to bodily symptoms such as those in Table 8.9, which in turn intensifies the symptoms (Kirmayer & Looper, 2006; Looper & Kirmayer, 2002). A common example of symptom amplification occurs when someone with a headache pays attention to the headache—and, invariably, the pain worsens.

Body dysmorphic disorder—a preoccupation with a *perceived* bodily defect—is the only somatoform disorder that does not include an actual somatic symptom.

The somatoform disorders involve dissociation; in these disorders, the processes of sensation and perception of bodily functioning are not integrated, but rather have become separated or altered. Somatoform disorders and dissociative disorders are classified separately only because of the bodily aspect of somatoform symptoms, but some researchers suggest that they should be combined into one category (Kihlstrom, 2001).

Somatoform disorders
A category of psychological disorders characterized by complaints about physical well-being that cannot be entirely explained by a medical condition, substance use, or another psychological disorder.

Table 8.9 ▶ Common Bodily Complaints of Patients with Somatoform Disorders

• Muscle and joint pain	• Palpitations
• Lower back pain	• Irritable bowel
• Tension headache	• Dizziness
• Atypical facial pain	• Insomnia
• Chronic fatigue	• Non-ulcer dyspepsia (indigestion)
• Non-cardiac chest pain

Symptoms of somatoform disorders have existed for millennia and were written about in the *Papyrus Ebers*, an ancient Egyptian medical document dating to 1600 B.C.E. However, the Egyptians believed that these symptoms had an underlying medical cause.

Somatization disorder (SD)

A somatoform disorder characterized by multiple physical symptoms that are medically unexplained and impair an individual's ability to function.

Pain disorder

A somatoform disorder that occurs when psychological factors significantly affect the onset, severity, or maintenance of significant pain.

Somatization Disorder

The hallmark of **somatization disorder (SD)** is multiple physical symptoms that are medically unexplained and impair an individual's ability to function (American Psychiatric Association, 2000). For example, Anna O.'s eye problems and her cough were both physical symptoms that impaired her daily life and that doctors could not explain. In this section we examine what somatization disorder is, and the various factors that are known to contribute to the disorder.

What Is Somatization Disorder?

To be diagnosed with SD according to DSM-IV-TR criteria, the individual must have had each of four different types of medically unexplained symptoms: pain symptoms, gastrointestinal symptoms, sexual symptoms, and pseudoneurological symptoms (the prefix *pseudo*—is used to indicate that the symptoms are similar to those of neurological disorders, but they do not have a neurological or other medical cause). Table 8.10 lists the DSM-IV-TR diagnostic criteria for SD.

As noted in Criterion C(2), sometimes people with SD *do* have a medical problem. In those cases, the clinician diagnoses SD only if the symptoms are more extreme than what would be expected based on the medical assessment. SD must be distinguished from neurological disorders, such as multiple sclerosis, other medical problems, and various other psychiatric disorders, including anxiety disorders and *pain disorder*.

According to DSM-IV-TR, **pain disorder** occurs when psychological factors significantly affect the onset, severity, or maintenance of significant pain (American Psychiatric Association, 2000). For a clinician to arrive at a diagnosis of pain disorder, the pain must cause significant distress or impair functioning, and malingering or factitious disorder must be ruled out. In some cases of pain disorder, examiners

Table 8.10 ▶ DSM-IV-TR Diagnostic Criteria for Somatization Disorder

- A.** A history of many physical complaints beginning before age 30 years that occur over a period of several years and result in treatment being sought or significant impairment in social, occupational, or other important areas of functioning.
- B.** Each of the following criteria must have been met, with individual symptoms occurring at any time during the course of the disturbance:
- (1) *four pain symptoms*: a history of pain related to at least four different sites or functions (e.g., head, abdomen, back, joints, extremities, chest, rectum, during menstruation, during sexual intercourse, or during urination)
 - (2) *two gastrointestinal symptoms*: a history of at least two gastrointestinal symptoms other than pain (e.g., nausea, bloating, vomiting other than during pregnancy, diarrhea, or intolerance of several different foods)
 - (3) *one sexual symptom*: a history of at least one sexual or reproductive symptom other than pain (e.g., sexual indifference, erectile or ejaculatory dysfunction, irregular menses, excessive menstrual bleeding, vomiting throughout pregnancy)
 - (4) *one pseudoneurological symptom*: a history of at least one symptom or deficit suggesting a neurological condition not limited to pain (conversion symptoms such as impaired coordination or balance, paralysis or localized weakness, difficulty swallowing or lump in throat, aphonia [loss of voice], urinary retention, hallucinations, loss of touch or pain sensation, double vision, blindness, deafness, seizures; dissociative symptoms such as amnesia; or loss of consciousness other than fainting)
- C.** Either (1) or (2):
- (1) after appropriate investigation, each of the symptoms in Criterion B cannot be fully explained by a known general medical condition or [as] the direct effects of a substance (e.g., a drug of abuse, a medication)
 - (2) when there is a related general medical condition, the physical complaints or resulting social or occupational impairment are in excess of what would be expected from the history, physical examination, or laboratory findings.
- D.** The symptoms are not intentionally feigned or produced (as in Factitious Disorder or Malingering).

cannot identify a medical cause for the pain; in other cases, a medical cause may underlie the pain, but psychological factors contribute significantly to the patient's experience of it. When the pain can be diagnosed as arising *predominantly* from a medical condition, pain disorder will not be diagnosed on Axis I, but the medical condition will be noted on Axis III, along with the specific location of the pain, such as the lower back (American Psychiatric Association, 2000).

Both pain disorder and somatization disorder involve genuine—as opposed to feigned—pain to which psychological factors are thought to contribute. However, SD requires that the individual have a history of four different locations of significant pain (as well as other types of bodily symptoms), whereas pain disorder requires only one location of significant pain (American Psychiatric Association, 2000).

Many laboratory tests and visits to doctors may be required to rule out other medical and psychological diagnoses, which is necessary before a diagnosis of SD can be made. When patients have more than one physical problem, arriving at such a diagnosis can be even more complicated and take even longer (Hilty et al., 2001). Table 8.11 lists additional facts about SD.

Table 8.11 ► Somatization Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none">• An individual's symptoms rarely meet the stringent diagnostic criteria for SD; survey studies have found that at most approximately 1% of people will receive this diagnosis in their lifetimes.• Although infrequent, SD is nonetheless a serious problem in medical settings; patients with this disorder use three times as many outpatient medical services and cost nine times more to treat than people who do not have this disorder (Hollifield et al., 1999).
Comorbidity
<ul style="list-style-type: none">• People with SD often have other psychological disorders, most frequently an anxiety disorder (particularly panic disorder), depression, or borderline personality disorder (to be discussed in Chapter 13).• Patients with SD who take benzodiazepines or narcotics for relief of bodily symptoms are at increased risk for developing a substance-related disorder (Holder-Perkins & Wise, 2001).
Onset
<ul style="list-style-type: none">• Initial symptoms of SD usually emerge between adolescence and age 30; menstrual difficulties may be the earliest symptom in women.
Course
<ul style="list-style-type: none">• The symptoms are chronic; they may fluctuate in location or in intensity (so that the criteria for SD are no longer met), but symptoms usually never completely disappear.• Patients with SD often take many medications and receive numerous medical tests and diagnoses (Holder-Perkins & Wise, 2001).• One study found that people in the United States who had this disorder spent, on average, 7 days in bed each month (Smith, Monson, & Ray, 1986).• Over the course of a year, 50% of patients improve at least enough so that their symptoms no longer meet the full diagnostic criteria (Creed & Barsky, 2004).
Gender Differences
<ul style="list-style-type: none">• Survey results differ: This disorder may occur equally often in women and men or may be as much as ten times more common among women as among men, depending on the survey (American Psychiatric Association, 2000; Toft et al., 2005).
Cultural Differences
<ul style="list-style-type: none">• The specific symptoms of patients with SD vary across cultures, and some ethnic groups have a higher prevalence of this disorder than others.
Source: Unless otherwise noted, the source is American Psychiatric Association, 2000.

In an effort to minimize their bodily symptoms, people with somatization disorder may restrict their activities. However, inactivity can create additional symptoms (such as back pain) or make existing symptoms worse (such as increased heart rate or difficulty breathing).

People with SD may avoid certain activities that they believe are associated with their bodily symptoms, such as any type of exercise. In so doing, patients attempt to minimize the physical sensations associated with the disorder. Unfortunately, they then become so out of shape that even normal daily activities, such as walking to the store from the parking lot, may lead them to experience bodily symptoms, creating a vicious cycle of avoidance and increased bodily symptoms. For people with SD, these symptoms impair daily life, which is what happened to Edward in Case 8.5.

CASE 8.5 ► FROM THE OUTSIDE: Somatization Disorder

As an infant, Edward had scarlet fever and a mild form of epilepsy, from which he recovered. By school age, he was complaining of stomachaches and joint pain and often missed school. There were many doctors, but no dire diagnosis: Edward was healthy, but many commented, a somewhat lonely and serious little boy.

Through high school and college Edward capitalized on those traits, achieving high grades and going into the insurance business. At forty-five, he is plagued by mysterious symptoms—heart palpitations, dizziness, indigestion, pain in his shoulders, back, and neck, and fatigue—and lives with his parents. His physical disabilities have made it impossible for Edward to hold a job, and his engagement was broken off. He remains on disability and spends much of his time in and out of hospitals undergoing various tests and procedures.

(Cantor, 1996, p. 54)

Criticism of the DSM-IV-TR Criteria

The DSM-IV-TR criteria for SD have been criticized on several grounds. First, the diagnosis is based on a simple counting of symptoms, so that each symptom is treated as equally important, regardless of how long it has persisted or how severe it is (Criterion B). However, some symptoms are more disabling than others, and chronic symptoms are likely to be more disabling than transient ones. Moreover, the minimum number of each type of symptom needed for the diagnosis was not based on research, but rather was set arbitrarily by the DSM-IV committee. That said, there is a simple defense of the method of counting symptoms used in DSM-IV-TR: studies find that the greater the number of medical symptoms an individual has, the more impaired he or she is likely to be (Barsky, Orav, & Bates, 2005; Jackson et al., 2006).

Second, the criteria do not address patients' behaviors nor their beliefs or attributions about their bodily symptoms (Holder-Perkins & Wise, 2001). Such factors are incorporated into the diagnostic criteria for panic disorder (see Chapter 7), and in some ways, SD is similar to panic disorder: Both involve a preoccupation with

the body, and as we shall see, both involve catastrophic thinking about aspects of bodily functioning.

Third, for most patients with SD, their bodily symptoms—or at least some of them—may be better explained by a different psychological disorder, such as depression, an anxiety disorder, or a personality disorder, which makes the additional diagnosis of SD unnecessary. For instance, gastrointestinal symptoms may arise from significant anxiety. DSM-IV-TR does not distinguish between an individual who has enough physical symptoms to meet Criterion B but no comorbid psychological disorder and an individual for whom some symptoms are directly related to a comorbid disorder.

Understanding Somatization Disorder

Like other psychological disorders, somatization disorder can be fully understood only by considering multiple types of factors. These factors include genetics, bodily preoccupation, symptom amplification and catastrophic thinking, and other people's responses to illness. Let's examine the various factors and how they influence one another.

Neurological Factors: Genetics

Most of the progress in understanding the neurological factors that underlie SD has been in the area of genetics. For example, in a large-scale twin study, researchers found that genetic effects may account for as much as half of the variability in SD (Kendler et al., 1995). Note, however, that this finding does not imply that the disorder itself is necessarily inherited; it could be that temperament or other characteristics that are influenced by genetics predispose a person to develop the disorder in certain environments. (This same point can be made about most findings that link genes to disorders.) Kendler and colleagues (1995) also reported that characteristics of families have no consistent effect on whether members of the family develop this disorder. This finding suggests that—in addition to genes—specific experiences of an individual, not shared experiences among members of a family, affect whether a person develops the disorder.

An interesting hint about how genes might affect SD came from a study of relatives of people with another somatoform disorder, *hypochondriasis* (a preoccupied belief that the individual has serious illness, despite negative medical tests; this disorder was mentioned earlier, and will be discussed in more detail shortly). Researchers found that SD was more frequent in the relatives of people with hypochondriasis, compared to relatives of control participants (Fallon et al., 2000; Noyes et al., 1997). This finding might suggest an underlying genetic link between SD and hypochondriasis, which is consistent with the fact that both disorders involve abnormal attention to bodily symptoms.

Psychological Factors: Misinterpretation of Bodily Signals

Like all somatoform disorders, SD involves bodily preoccupation and symptom amplification, as well as catastrophic thinking—in this case, about physical sensations or fears of illness. These patients may believe, for example, that headaches indicate a brain tumor. Their mental processes—particularly attention—focus on bodily sensations, including the beating of their hearts (Barsky, Cleary, et al., 1993, 1994), leading to symptom amplification and catastrophic thinking. These effects also arise in part from faulty beliefs about their bodies and bodily sensations. For example, people with SD may erroneously believe that health is the absence of *any* uncomfortable physical sensations (Rief & Nanke, 1999). However, most people without SD experience some somatic symptoms, at least some of the time. The difference is that people who do not have a somatoform disorder do not habitually develop catastrophic misinterpretations of such sensations. Among a group of healthy college students, for example, 81% experienced at least one somatic symptom in a 3-day period (Gick & Thompson, 1997). For people with SD, their erroneous beliefs about health and illness can increase their level of arousal, which—because of their increased attention to bodily symptoms—can lead to further bodily sensations that are then misinterpreted (Mayou & Farmer, 2002).

Social Factors

Social factors that can contribute to SD include significant social stressors, the modeling and reinforcement of illness behavior, and cultural influences on symptoms. Let's examine these social factors.

Social Stress In many cases, somatoform disorders, including SD, develop after the death of a loved one or after another significant social stressor (Hiller, Rief, & Fichter, 2002). This is what happened to Anna O. after her father died. Somatic symptoms serve as a coping strategy, leading the person to focus attention away from the stressor and onto a bodily sensation.

Social Learning Observational learning can explain the finding that people with SD are more likely than those without the disorder to have had an ill parent (Bass & Murphy, 1995; Craig et al., 1993). In these cases, an ill parent may have inadvertently modeled illness behavior.

Moreover, operant conditioning can also be at work, when people provide reinforcement for an individual's illness behavior: During the patient's childhood, family members may have unintentionally reinforced illness behavior by paying extra attention to the child or buying special treats for the child when he or she was ill (Craig, 1978; Craig et al., 2004; Holder-Perkins & Wise, 2001). Similarly, adults with SD may be reinforced for their symptoms by the attention of medical personnel, family, friends, or coworkers (Maldonado & Spiegel, 2001).

Cultural Influences on Symptoms In many cultures, including that of the United States, somatic symptoms may be regarded as an acceptable way to express helplessness, such as by those who experienced abuse during childhood (Walling et al., 1994). The use of somatic symptoms to express helplessness may explain the bodily symptoms of Anna O. and other upper-middle class women of the Victorian era, whose lives were severely restricted by societal conventions. However, although symptoms of SD occur around the globe, the nature of the symptoms differs across cultures. For instance, symptoms of burning hands or feet are more common in Africa and South Asia than in Europe or North America (American Psychiatric Association, 2000).

In addition, culture influences the prevalence of SD: Although Hispanics in general are not more likely than others to develop the disorder, Puerto Ricans are ten times more likely to do so than the general U.S. population (Canino et al., 1992; Escobar, 1987; Shrout et al., 1992). Moreover, economic status influences prevalence. In contrast to Vienna during Anna O.'s lifetime, people from lower SES groups today are more likely to develop the disorder than those from higher SES groups (Wool & Barsky, 1994). One possible explanation is that those in lower SES groups may feel more helpless.

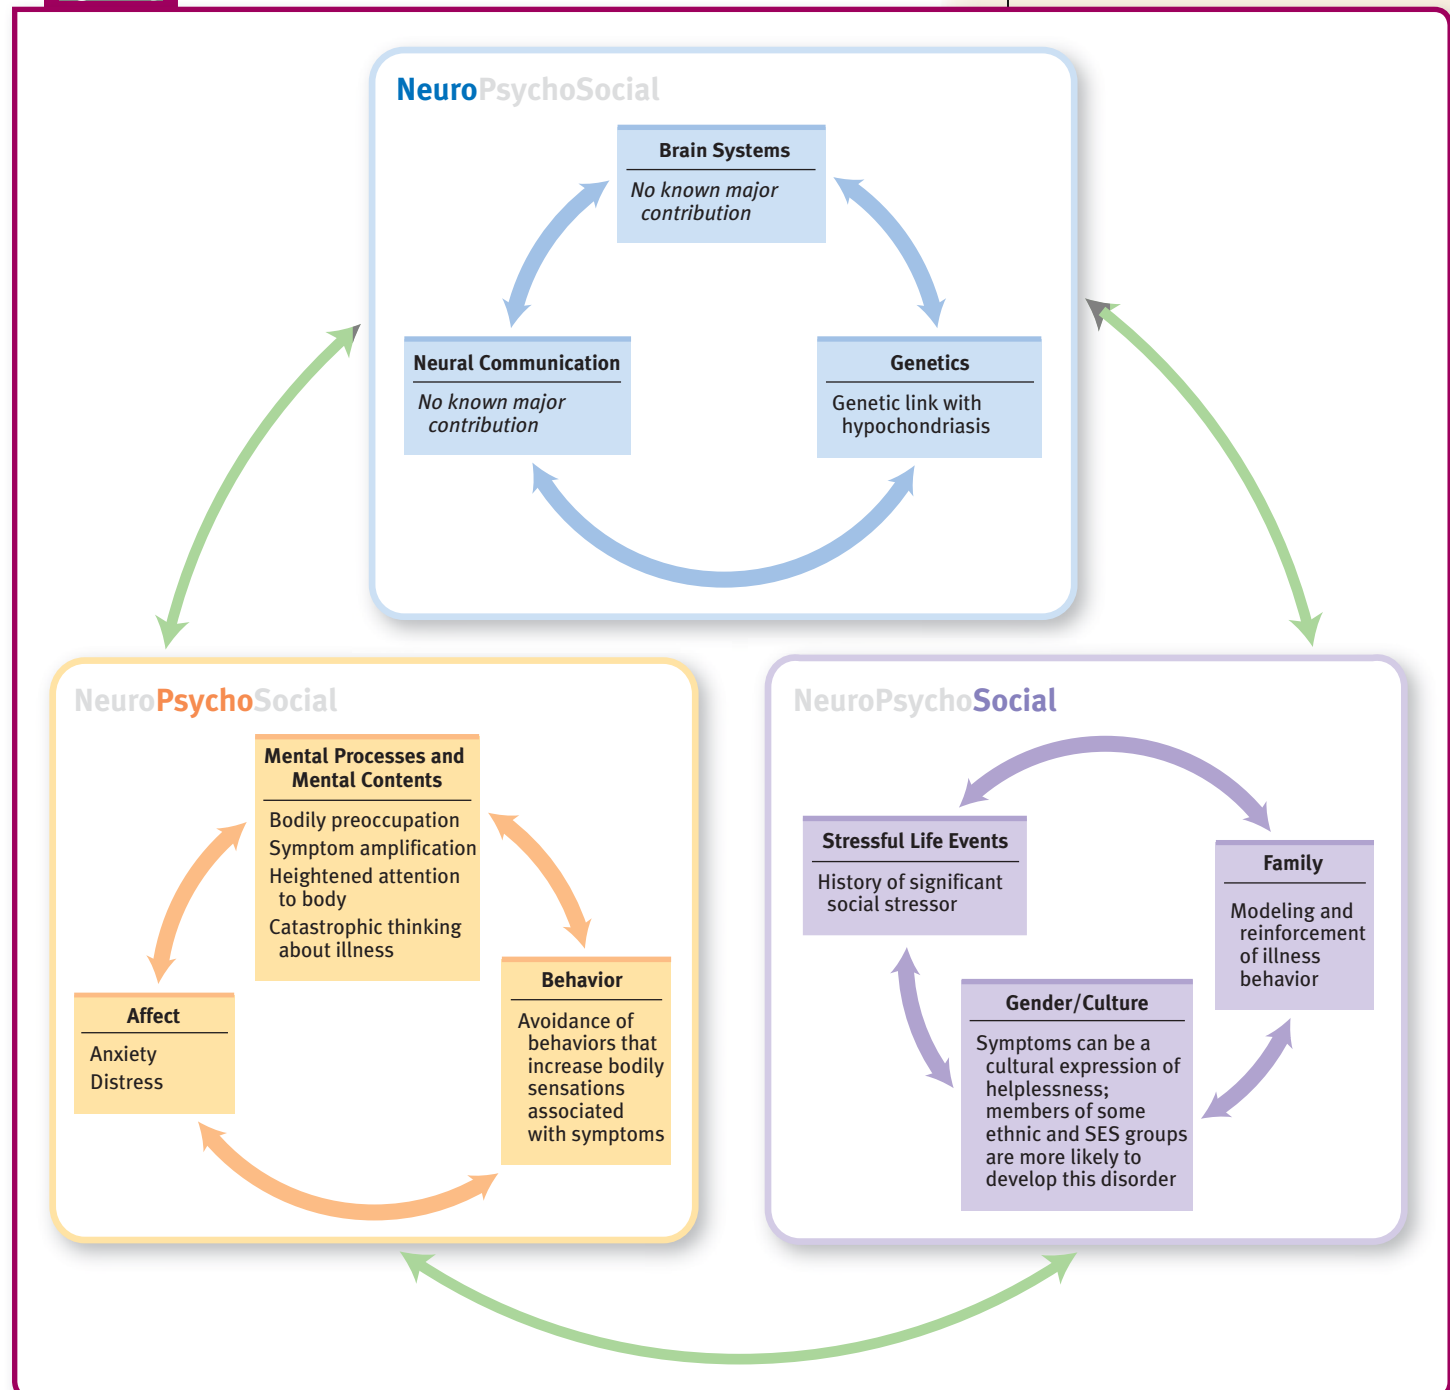

FEEDBACK LOOPS IN ACTION: Somatization Disorder

It is common for people with SD to have had a disease, illness, accident, or other form of trauma prior to developing the disorder. In fact, people with this disorder are more likely to report a history of childhood abuse than are other medical patients (Brown, Schrag, & Trimble, 2005). In individuals who are genetically predisposed to SD (neurological factor), the bodily sensations caused by an illness or accident are interpreted as signaling a catastrophic illness (psychological factor). In turn, this misinterpretation may cause the person to change his or her behavior in a way that ultimately becomes dysfunctional, restricting activities and straining relationships.

Such misinterpretations may initially grow out of modeling. For example, consider that children whose parents have chronic pain are more likely to report abdominal pain themselves and to use more pain relievers than a comparison group of children (Jamison & Walker, 1992). These children's experiences with their ill parent (social factor) may influence their body via their brains (perhaps they have more stomach acid because they are more anxious and stressed; neurological factor), their attention to and attributions for bodily sensations (psychological factors), and their reporting of pain (social factor).

Moreover, a patient's symptoms may have been unintentionally reinforced by friends and family (social factor). A similar shift in interpretation of sensations (psychological factor) can occur after stressful life events (social factor). In addition, frustrating interactions with health care providers, family members, or friends can increase stress (social factor). As with panic disorder (see Chapter 7), the physiological arousal that occurs in response to stress can increase troubling bodily sensations that then become the focus of preoccupations (see Figure 8.3).

Figure 8.3

8.3 ► Feedback Loops in Action: Somatization Disorder

Conversion Disorder

Conversion disorder involves sensory or motor symptoms that do not correspond to those that arise from known medical conditions. We'll first explore what conversion disorder is, then review criticisms of the criteria for this disorder and discuss whether it is more similar to somatoform disorders or dissociative disorders. Following this, we review the neurological, psychological, and social factors that can lead to this disorder.

What Is Conversion Disorder?

Patients who have conversion disorder do not consciously produce the symptoms they experience (as in factitious disorder or malingering) and these patients are significantly distressed or their functioning is impaired by the symptoms (see Table 8.12). Conversion disorder is similar to SD in that both involve physical symptoms that are not explained by a medical condition; however, conversion disorder is limited to sensory and motor symptoms that appear to be neurological (that is, related to the nervous system) but, on closer examination, do not correspond to effects of known neurological pathways (see Figure 8.4). A diagnosis of conversion disorder can only be made after physicians rule out all possible medical causes, and this process can take years.

Conversion disorder is characterized by three types of symptoms (American Psychiatric Association, 2000; Maldonado & Spiegel, 2001):

- **Motor symptoms.** Examples include tremors that worsen when attention is paid to them, tics or jerks, muscle spasms, swallowing problems, staggering, and paralysis (sometimes referred to as *pseudoparalysis*, which may also involve significant muscle weakness).
- **Sensory symptoms.** Examples include blindness, double vision, deafness, auditory hallucinations, and lack of feeling on the skin that doesn't correspond to what is produced by malfunctioning of an actual nerve path.
- **Seizures.** Examples include twitching or jerking of some part of the body and loss of consciousness with uncontrollable spasms of the large muscles in the body, causing the person to writhe on the floor. These seizures are often referred to as *pseudoseizures* because they do not have a neurological origin and are not usually affected by seizure medication. Pseudoseizures are likely to occur when other

Table 8.12 ▶ DSM-IV-TR Diagnostic Criteria for Conversion Disorder

- | |
|---|
| A. One or more symptoms or deficits affecting voluntary motor or sensory function that suggest a neurological or other general medical condition. |
| B. Psychological factors are judged to be associated with the symptom or deficit because the initiation or exacerbation of the symptom or deficit is preceded by conflicts or other stressors. |
| C. The symptom or deficit is not intentionally produced or feigned (as in Factitious Disorder or Malingering). |
| D. The symptom or deficit cannot, after appropriate investigation, be fully explained by a general medical condition, or by the direct effects of a substance, or as a culturally sanctioned behavior or experience. |
| E. The symptom or deficit causes clinically significant distress or impairment in social, occupational, or other important areas of functioning or warrants medical evaluation. |
| F. The symptom or deficit is not limited to pain or sexual dysfunction, does not occur exclusively during the course of Somatization Disorder, and is not better accounted for by another mental disorder. |

Conversion disorder

A somatoform disorder that involves sensory or motor symptoms that do not correspond to symptoms that arise from known medical conditions.

Figure 8.4**8.4 ► Conversion Disorder: Glove**

Anesthesia Patients suffering from conversion disorder have sensory or motor symptoms that at first may appear to be neurological but on further investigation do not correspond to true neurological damage. One example is *glove anesthesia*, in which the person reports that his or her hand—and only the hand—has no sensation, as shown in (a). However, the neural pathways that would create such an anesthesia in the hand would also create a lack of sensation in the arm (b); the color-coded regions show the areas served by different nerves. Thus, conversion disorder may be the appropriate diagnosis when a patient reports glove anesthesia in the absence of anesthesia of the arm.

people are present; patients don't hurt their heads, bite their tongues, or urinate, as during true seizures.

Anna O. had both motor conversion symptoms (paralysis of her neck, arm, and legs) and sensory conversion symptoms (problems with vision, a lack of sensation in her elbows). Breuer did not report any seizure-like symptoms.

In conversion disorder, muscle symptoms do not correspond to what would be produced by the relevant nerve pathways, but rather they arise from the patients' *perception* of what would happen if certain nerve pathways were disrupted. Thus, a patient may not be able to write but can scratch an itch, which would be impossible with true paralysis of the hand muscles. Similarly, when the sensory symptom of blindness occurs in conversion disorder, medical tests reveal that all parts of the visual system function normally. This was true for Mary, described in Case 8.6.

CASE 8.6 ► FROM THE INSIDE: Conversion Disorder

On graduating from high school, Mary decided to enter a convent and by the age of twenty-one had taken her vows of poverty, chastity, and obedience. This came as a shock to her family who, although they were practicing Catholics, had been far from religious. "I had a great need to help people and do something spiritual and good," Mary recalls. . . .

For the first decade she enjoyed the sense of community and the studious aspect of convent life. . . . But as time went on she became disenchanted with the church, which she felt was "out of touch with real people. . . . The church required blind obedience and no disagreement."

Mary began feeling nervous and anxious. She was rarely sick, but one day [when she was 36 years old] developed soreness in the back of her eye. Every time she moved it, she'd feel pins and needles. . . . By the fourth day she couldn't see out of one eye. A neurologist said it was optic neuritis, a diagnosis of nerve inflammation of unknown origin. She was hospitalized and given cortisone, but her sight didn't improve.

. . . Mary took a leave of absence and spent the good part of a year at a less stressful convent in the countryside. She began meeting regularly with a psychologist. . . . "I discovered I was a perfectionist, overworking to avoid my growing doubts." . . . Her eyesight gradually came back, and shortly after that she left the church.

. . . "During that period in my life I was undergoing deep psychological trauma. I was so unhappy, and I literally didn't want to see," she says. "I believed then, as I do today, that the body was telling me something, and I had to listen to it."

(Cantor, 1996, pp. 57–58)

People with conversion disorder may react in radically different ways to their symptoms and to what they might imply: Some seem indifferent, whereas others respond dramatically. Anna O.'s response was "a slight exaggeration, alike of cheerfulness and gloom; hence she was sometimes subject to moods" (Breuer & Freud, 1895/1955, p. 21). Table 8.13 provides more facts about conversion disorder.

Criticisms of the DSM-IV-TR Criteria

Some researchers have suggested that conversion disorder is not a distinct disorder, but rather a variant of SD; these researchers point out that both disorders may involve the bodily expression of psychological distress (Bourgeois et al., 2002). In fact, the diagnosis of conversion disorder, and its placement among the somatoform disorders, is controversial. Many researchers believe that conversion symptoms in general, and pseudoseizures in particular, are more like dissociative symptoms than like symptoms of other somatoform disorders (Kihlstrom, 2001; Mayou

Table 8.13 ▶ Conversion Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none"> Conversion disorder is very rare, with prevalence estimates from 0.01% to 0.05% in the general population and up to 3% of those who are referred to outpatient mental health services.
Comorbidity
<ul style="list-style-type: none"> Studies have found that up to 85% of people with conversion disorder also have major depressive disorder (Roy, 1980; Ziegler, Imboden, & Meyer, 1960). Patients with conversion disorder may also have a neurological disorder, such as multiple sclerosis or a condition that produces true seizures (Maldonado & Spiegel, 2001). A history of sexual or physical abuse is common among patients with conversion disorder (Bowman, 1993).
Onset
<ul style="list-style-type: none"> This disorder frequently begins during late childhood or early adolescence, and rarely appears after age 35. Symptoms typically emerge suddenly after a significant stressor, such as the loss of a loved one, or a physical injury (American Psychiatric Association, 2000; Stone et al., 2009). For men, the disorder is most likely to develop in the context of the military or industrial accidents (American Psychiatric Association, 2000; Maldonado & Spiegel, 2001).
Course
<ul style="list-style-type: none"> Symptoms typically last only a brief period of time. Between 25% and 67% of those with the disorder have a recurrence up to 4 years later (American Psychiatric Association, 2000; Maldonado & Spiegel, 2001).
Gender Differences
<ul style="list-style-type: none"> Conversion disorder is two to ten times more common among women than men (Bowman, 1993; Raskin, Talbott, & Meyerson, 1966). Women with the disorder may later develop SD. Men with the disorder may also have antisocial personality disorder (to be discussed in Chapter 13).
Cultural Differences
<ul style="list-style-type: none"> Conversion disorder is more common in rural populations, among those from lower SES backgrounds, and among those less knowledgeable about psychological and medical concepts. It is also more common in developing countries than in industrialized countries, and as a country becomes industrialized, the prevalence of conversion disorder decreases. Small "epidemics" of conversion disorder have been reported in countries undergoing cultural change or significant stress (Piñeros, Roselli, & Calderon, 1998; Cassady et al., 2005).
Source: Unless otherwise noted, the source is American Psychiatric Association, 2000.

et al., 2005). As they note, dissociation can affect not only memory and the sense of self, but can also disrupt the integration of sensory or motor functioning.

Other researchers argue that conversion disorder doesn't really exist, but is a type of factitious disorder: The patient is creating a socially sanctioned way to enact a sick role, thereby manipulating others and avoiding responsibilities (Celani, 1976). However, according to the DSM-IV-TR criteria, the symptoms would meet the criteria for factitious disorder only if they are voluntarily—that is, consciously—created. In many cases of conversion disorder, the symptoms do not appear to be consciously created, and so factitious disorder would not be an appropriate diagnosis.

Understanding Conversion Disorder

Research on neurological factors in conversion disorders focuses on how brain systems operate differently in people with the disorder. Psychological factors associated with the disorder include the role of self-hypnosis and dissociation. And a key social factor is the role of intense stressors. Unfortunately, not enough is known to understand how the various factors might influence each other.

Neurological Factors

By far, the bulk of neurologically oriented studies of conversion disorder have examined brain systems.

Brain Systems When contemplating the diagnosis of conversion disorder, clinicians must rule out simple malingering or faking of symptoms. (Patients are sometimes motivated to fake such illnesses in order to collect insurance, disability payments, and so on.) Could all cases of conversion disorder just be faking? Neuroimaging findings suggest that muscle weakness arising from conversion disorder is not the same as consciously simulated muscle weakness. For example, Stone and colleagues (2007) scanned the brains of patients with conversion disorder and of healthy controls while their ankles were flexed. The patients with conversion disorder all reported weakness in the manipulated ankle prior to the study; during the study, participants in the control group were asked to pretend that their ankles were weak. The results were clear: Some brain areas were more activated in the patients than in the controls (such as the insula, which is involved in registering input from the body) and some brain areas (including areas in the frontal lobes) were less activated in the patients than in the controls. These findings are good evidence that the patients were not simply faking their disorder.

In addition, some patients with chronic pain develop sensory deficits, a kind of “psychological” anesthesia. These patients often also have weakness (and sometimes paralysis) of a limb, and they are typically classified as having both conversion disorder and a pain disorder. In one study aimed at discovering whether such symptoms reflect changes in how brain systems operate, researchers scanned the brains of four such patients using fMRI, while sharp plastic fibers were pressed into the skin (Mailis-Gagnon et al., 2003). These patients had apparent sensory deficits in only one limb, and thus the researchers could directly compare stimulation of the normal and affected limbs. When the researchers stimulated the normal limb, the sharp plastic fibers activated a brain network that registers pain (which includes the thalamus, the anterior cingulate cortex, the insula, and part of the frontal lobe), as is normal. In contrast, this network was not activated when the researchers stimulated the affected limb, as is shown in Figure 8.5. Moreover, some brain areas—the somatosensory cortex (both the primary and secondary areas) and parts of the parietal and frontal lobes—were activated less than normally when the researchers stimulated the affected limb. These findings indicate that the “psychological” anesthesia actually affected the brain and inhibited activation in the brain areas that register sensation and pain.

Another neuroimaging study examined patients with conversion disorder who had a loss of sensation and motor control in one hand. These researchers used a vibration device to stimulate both hands while recording blood flow in the brain. They found decreased blood flow in the thalamus and the basal ganglia on the side

8.5 ► Brain Activation in Conversion Disorder: Healthy Limb Versus Affected Limb

Limb Brain areas activated when the skin of the healthy, nonaffected limb was stimulated (top row) compared to those activated when the skin of the affected limb was stimulated (bottom row); arrows show the key areas of activation (Mailis-Gagnon et al., 2003). It's clear that the scans in the bottom row show much less activation.

Figure 8.5

opposite the affected hand (each hemisphere of the brain controls and registers sensations from the opposite side of the body); these brain areas are involved in attention and motor control, respectively. When retested 2–4 months later, after the symptoms had disappeared, the patients' brains functioned normally (Vuilleumier et al., 2001). These findings suggest that the decreased sensitivity to stimuli that can occur in conversion disorder arises from decreased activity of sensory brain structures. Thus, at least for these patients, the disorder directly reflects brain events; it is not some form of malingering or faking of symptoms.

However, other researchers report that the brain *does* respond even though conscious perception is absent (for example, see Hoechstetter et al., 2002; Lorenz, Kunze, & Bromm, 1998). Taken together, the findings suggest that conversion disorder is not a direct consequence of impaired brain areas that *register* peripheral sensations, but rather reflects abnormal operation of brain areas that *interpret* sensations and *manage* other brain areas (that is, areas that are involved in “executive functions”). At least in some cases, abnormal processing in brain areas responsible for executive functions might inhibit brain areas that process sensation and pain or that produce movements, which in turn causes them to fail to function properly.

Finally, it is important to note that conversion disorder is sometimes incorrectly diagnosed. One study, for example, found that many patients who suffered seizures and were diagnosed with conversion disorder in fact had neurological abnormalities in one cerebral hemisphere, typically the right (Devinsky, Mesad, & Alper, 2001). Thus, in some cases, the symptoms of conversion disorder may reflect, at least in part, underlying medical problems. In fact, the results of one study of patients diagnosed with conversion motor paralysis suggest that as many as half of those patients may have a genuine medical problem (Heruti et al., 2002).

Genetics At least in some cases, conversion disorder may run in families, but it is difficult to disentangle the role of genes from that of modeling the behavior of family members (Schulte-Korne & Remschmidt, 1996). For example, if a parent never uses one hand, it is possible that a child may come to imitate that behavior, and thus not use that hand.

Psychological Factors: Self-Hypnosis?

There is no generally accepted explanation for how psychological factors might produce the selective bodily symptoms in conversion disorder (Halligan, Bass, & Wade, 2000). But self-hypnosis offers one possible explanation—that the disorder is the result of unintended self-hypnotic suggestion. According to this theory, patients have, consciously or unconsciously, “suggested” to themselves that they have symptoms. Thus, those who have a sensory conversion disorder may unknowingly hypnotize themselves so that they are not consciously aware of the sensations in some part of their body (Kozłowska, 2005); that is, such sensations have become dissociated. This theory receives support from the fact that people with conversion disorder are unusually hypnotizable (Roelofs, Hoogduin, et al., 2002).

The theory that conversion disorder results from self-hypnosis is supported by the finding that areas of the brain activated by hypnotically induced paralysis are similar to those activated by paralysis in patients with conversion disorder (Halligan et al., 2000; Oakley, 1999). The self-hypnosis explanation also is consistent with neodissociation theory, discussed in the section on dissociative amnesia: The sensory system is somehow disconnected from the executive monitoring system, creating the conscious experience of a lack of sensory input (Hilgard, 1994). Thus, conversion symptoms can be considered to be errors in the cognitive processing of sensation and movement (Kozłowska, 2005; Oakley, 1999).

Social Factors: Stress Response

Life stressors, such as combat, can trigger conversion disorder. Moreover, the greater the severity or number of stressors, the more severe the conversion symptoms (Roelofs et al., 2005). As we saw with SD, somatic symptoms can be a culturally accepted way to express feelings of helplessness (Celani, 1976), which may explain why some soldiers develop conversion disorder in combat. Conversion disorder can also be a way to obtain the attention associated with being sick. This was certainly true for Anna O., and for many other women of the Victorian era.

Hypochondriasis

People who are diagnosed with **hypochondriasis** are preoccupied with a fear or belief that they have a serious disease, but this preoccupation arises because they have misinterpreted their bodily sensations or symptoms (American Psychiatric Association, 2000). Despite the fact that physicians cannot identify a medical problem, patients with hypochondriasis persist in clinging strongly to their conviction that they have a serious disease. Although people with SD and those with hypochondriasis share a focus on bodily symptoms, only those with hypochondriasis believe that they have a serious illness despite reassurance from doctors. Moreover, people with hypochondriasis do not see that there are other possible explanations for their sensations (Smeets, de Jong, & Mayer, 2000).

What Is Hypochondriasis?

Patients with hypochondriasis may or may not realize that their worries are excessive for the situation; when they do not, they are said to have *poor insight* into their condition. Consider a man who sees floating “spots” and does not believe his eye doctor when told that such *floaters* are normal and nothing to worry about. The man probably doesn’t think that the doctor is lying about the spots, but he may believe that the doctor didn’t do a thorough enough eye examination; he may think that the floaters indicate that he is going blind or that he has a tumor. His worries about this problem are distressing and preoccupying to the point that he’s functioning less well at work—not because of the floaters, but because of his frequent thoughts about the floaters. To be diagnosed with this disorder in DSM-IV-TR, this

Symptoms of conversion disorder may be more common after significant psychological stressors, such as military combat. This soldier is displaying muscular spasms as part of his conversion disorder. Such symptoms among soldiers are thought to resolve a conflict between their loyalty to comrades and their fear of battle: Soldiers with such symptoms are unable to fight (Spiegel, 1974).

Hypochondriasis

A somatoform disorder marked by a preoccupation with a fear or belief of having a serious disease, but this preoccupation arises because the individual has misinterpreted his or her bodily sensations or symptoms.

Table 8.14 ▶ DSM-IV-TR Diagnostic Criteria for Hypochondriasis

- A.** Preoccupation with fears of having, or the idea that one has, a serious disease based on the person's misinterpretation of bodily symptoms.
- B.** The preoccupation persists despite appropriate medical evaluation and reassurance.
- C.** The belief in Criterion A is not of delusional intensity (as in Delusional Disorder, Somatic Type [discussed in Chapter 12]) and is not restricted to a circumscribed concern about appearance (as in Body Dysmorphic Disorder [discussed later in this chapter]).
- D.** The preoccupation causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- E.** The duration of the disturbance is at least 6 months.
- F.** The preoccupation is not better accounted for by Generalized Anxiety Disorder, Obsessive-Compulsive Disorder, Panic Disorder [all discussed in Chapter 7], a Major Depressive Episode [Chapter 6], Separation Anxiety [Chapter 14], or another Somatoform Disorder.

kind of preoccupation with a perceived health problem must cause significant distress or impair the person's functioning in some way and must have continued for at least 6 months (see Table 8.14). Additional facts about hypochondriasis are presented in Table 8.15.

Like people with SD, those with hypochondriasis don't appreciate that even healthy people sometimes have aches and pains and other bodily discomforts. Instead, they unrealistically believe that having "good health" implies not having any unpleasant bodily symptoms (Barsky, Coeytaux, et al., 1993), as does the woman in Case 8.7.

CASE 8.7 ▶ FROM THE INSIDE: Hypochondriasis

I attended graduate school, held jobs, was married, had children. But my existence was peppered with episodes of illness. When the going got tough, I'd get sick. Or just the opposite: when things seemed to be going well, I'd come down with a symptom, or at least what I interpreted as one. It might be stomach pain, dizziness, black and blue marks, swollen glands, an achy heel. Anything. Whatever the symptoms, I always interpreted it as a precursor of some crippling illness: leukemia, Lou Gehrig's disease, scleroderma. I knew just enough about most diseases to cause trouble. Eventually I'd get past each episode, but it always took time—the cure a mysterious concoction of enough negative tests, a lessening of symptoms, some positive change in my life. And when the event was over, the realization that I was healthy and wasn't going to die, at least not immediately, was like a high, a reprieve, a new lease on life. That is, until the next time.

(Cantor, 1996, pp. 9–10)

Hypochondriasis and Anxiety Disorders: Shared Features

Hypochondriasis has many features in common with anxiety disorders. In fact, hypochondriasis and anxiety disorders are so similar that some researchers have advocated moving hypochondriasis from the category of somatoform disorders to the category of anxiety disorders, and renaming it *health anxiety disorder* (Mayou et al., 2005). Let's compare hypochondriasis with some anxiety disorders.

Hypochondriasis, phobias, and panic disorder are all characterized by high levels of fear and anxiety, as well as a faulty belief of harm or danger. However, with hypochondriasis and panic disorder, the perceived danger is from an internal event that is thought to be producing a bodily sensation, whereas with phobias, it is from an external object (such as a snake) or a situation (such as giving a speech;

Table 8.15 ▶ Hypochondriasis Facts at a Glance

Prevalence
<ul style="list-style-type: none">• In the general population, hypochondriasis is rare and its prevalence is unknown. Among medical patients, 1–5% are diagnosed with this disorder (Magarinos et al., 2002).
Comorbidity
<ul style="list-style-type: none">• People with hypochondriasis also commonly suffer from an anxiety or depressive disorder or another somatoform disorder.
Onset
<ul style="list-style-type: none">• Typically, hypochondriasis begins during early adulthood (Fallon et al., 1993).• A stressful life event, such as the death of a loved one, can precipitate symptoms of hypochondriasis (Fallon & Feinstein, 2001).
Course
<ul style="list-style-type: none">• Over the course of a year, 50% of people with hypochondriasis improve at least to some degree (Creed & Barsky, 2004; Olde Hartman et al., 2009).• People most likely to recover fully from hypochondriasis do not have another psychological disorder; their symptoms developed quickly and are mild.
Gender Differences
<ul style="list-style-type: none">• Nothing definitive can be said about whether one gender is more likely to suffer from this disorder than the other; the handful of relevant studies found contradictory results (Creed & Barsky, 2004; Toft et al., 2005).
Source: Unless otherwise noted, the source is American Psychiatric Association, 2000.

Fava, Mangelli, & Ruini, 2001). People with panic disorder, phobias, and hypochondriasis all may try to avoid certain stimuli or situations; with panic disorder and hypochondriasis, what is avoided may be an elevated heart rate (Hiller, Rief, & Fichter, 2002).

In addition, both patients with hypochondriasis and those with obsessive-compulsive disorder (OCD) have obsessions and compulsions (Abramowitz & Braddock, 2006). In particular, patients with hypochondriasis obsess about possible illnesses or diseases they believe they might have. They may compulsively ask doctors, friends, or family members for reassurance or compulsively “check” their body for particular sensations. If someone excessively probes, prods, or touches certain body parts, he or she can create lumps or bruises, which are then interpreted as a new “symptom” of disease. As Internet use has increased over the last decade, people with some forms of hypochondriasis spend hours compulsively consulting medical Web sites. (It’s important to keep in mind that some medically related Internet chat rooms or Web sites can spread false or misleading information.)

Understanding Hypochondriasis

Let’s again consider the neuropsychosocial factors. Most research on understanding hypochondriasis has examined psychological factors. Neurological and social factors are only beginning to be the focus of research and so not enough is known to understand the feedback loops among the types of factors.

Neurological Factors

Neurological factors that are associated with hypochondriasis involve brain systems, neural communication, and genetics.

Brain Systems Perhaps the most informative study of the brain systems that underlie hypochondriasis compared patients with this disorder to normal controls and also to patients who either had panic disorder or OCD (van den Heuvel et al.,

David Young-Wolff/PhotoEdit Inc.

Because of their particular cognitive biases regarding health and illness, for people with hypochondriasis, simply reading about an illness or hearing about someone who is sick can lead to becoming preoccupied with similar symptoms or diseases in their own bodies.

2005). The three types of patients had their brains scanned while they indicated the color of various printed words. The trick was that some words were related to OCD (e.g., “dirty,” “messy”), and other words were related to symptoms of panic disorder (e.g., “crowd,” “faint”). The meanings of the words thus could be distracting, perhaps to different degrees, for the patients. One relevant result of this study was that the amygdala was activated in the OCD patients when they viewed OCD-related words, but it was not activated in the patients with hypochondriasis—which shows that the two disorders are not the same. Moreover, in general the brain activation pattern of patients with hypochondriasis more closely resembled that of patients with panic disorder than patients with OCD. But even here, the patterns of activation were not identical, which indicates that the disorders are probably not precisely the same.

Neural Communication Some researchers have suggested that the neurotransmitter serotonin does not function properly in at least some cases of hypochondriasis (King, 1990). As we’ll see in the section on treatment, there is some indirect support for this hypothesis, based on the observation that SSRIs (which selectively affect serotonin reuptake, as discussed in Chapter 4) appear to improve the disorder. That is, the mere fact that SSRIs can improve the symptoms is evidence that the symptoms arise, at least in part, from disruption of the activity of serotonin.

Genetics Results from one twin study suggest that genetic differences do contribute to hypochondriasis (Gillespie et al., 2000). These researchers found that genetics account for about a third of the variation in bodily symptoms that are not clearly related to a medical disorder. In addition, researchers have used genetic studies to examine the possible link between hypochondriasis and OCD; some studies find evidence for such a link (Bienvenu et al., 2000; Noyes, Happel & Yagla, 1999) and others don’t (Fallon et al., 2000). One possible reason for these conflicting results is that there may be different types of hypochondriasis, only one of which is related to OCD (Barsky, 1992).

Psychological Factors: Catastrophic Thinking About the Body

People with hypochondriasis have specific biases in their reasoning: Not surprisingly, given their disorder, they not only tend to seek evidence of health threats but also may fail to consider evidence that such threats are minimal or nonexistent (Salkovskis, 1996; Smeets, de Jong, & Mayer, 2000). For instance, a man with hypochondriasis who notices a bruise on his leg might interpret it as an indicator of leukemia rather than trying to remember whether he had recently bumped into something that could cause a black-and-blue mark.

In addition, people afflicted with hypochondriasis focus attention closely on unpleasant sensations, even if those sensations are relatively weak or infrequent. They commonly focus on the functioning of body parts (such as the stomach or the heart), minor physical problems (such as a sore throat), and ambiguous physical sensations (such as “aching veins”). Moreover, they interpret bodily sensations as abnormal, pathological, and symptomatic of disease (Barsky, 1992; Barsky et al., 2000). In fact, like patients with SD, patients with hypochondriasis may engage in *catastrophic thinking* about their physical sensations or fears of illness, just as the woman in Case 8.7 did when she interpreted physical sensations as signs of “crippling illness.” Furthermore, perhaps as a result of these attentional biases, people with hypochondriasis have better memory for health-related words than for non-health-related words (Brown et al., 1999).

As is the case with many anxiety disorders, people with hypochondriasis may engage in behaviors that temporarily reduce their anxiety. For example, they may repeatedly take their blood pressure, perform urine dipstick tests, feel body parts for cancerous lumps, or call their doctor about new symptoms. Such behaviors maintain their faulty beliefs and can, through negative reinforcement, sustain the anxiety in the long term.

David Young-Wolff/PhotoEdit Inc

People with hypochondriasis fear that they have a serious illness and do not believe their doctors when told that they are healthy. Such patients may then “doctor-shop”—consulting many doctors in search of one who will confirm the presence of an illness.

Social Factors: Stress Response

As with other somatoform disorders, stressful events can precipitate hypochondriasis (Fallon & Feinstein, 2001). In addition, people with hypochondriasis are more likely than people without the disorder to report having experienced traumatic sexual contact, physical violence, or major familial upheaval (such as their parents’ divorce) (Barsky, Wool, et al., 1994). In addition, through attention and concern, relatives and friends may unintentionally reinforce patients’ symptoms.

Body Dysmorphic Disorder

Body dysmorphic disorder (sometimes called *dysmorphophobia*) is diagnosed when someone is excessively preoccupied with a *perceived* defect or defects in appearance. The preoccupation is excessive because a defect is either imagined or slight. In this section we examine body dysmorphic disorder in detail—the DSM-IV-TR criteria and the factors that contribute to the disorder.

What Is Body Dysmorphic Disorder?

It’s a common experience to believe that a pimple on your forehead appears like a red beacon for others to see; many people will try to cover up or hide a pimple. It’s also common for individuals with a receding hairline to change their hairstyle to make the hair loss less noticeable. What isn’t common—and, in fact, signals a psychological disorder—is when an imperfection in appearance, even an imagined one, causes significant distress or takes up so much time and energy that daily functioning is impaired. These are the signs of body dysmorphic disorder. Table 8.16 lists the specific DSM-IV-TR diagnostic criteria for this disorder.

Common preoccupations for people with body dysmorphic disorder are thinning or excessive hair, acne, wrinkles, scars, complexion (too pale, too dark, too red, and so on), facial asymmetry, or the shape or size of some part of the face or body. The “defect” (or “defects”) may change over the course of the illness (Phillips, 2001). People with body dysmorphic disorder may think that others are staring at them or talking about a “defect.” Up to half of those with body dysmorphic disorder are delusional—that is, they believe their perception of a “defect” is accurate and not exaggerated (Phillips et al., 1994).

Table 8.16 ▶ DSM-IV-TR Diagnostic Criteria for Body Dysmorphic Disorder

- A.** Preoccupation with an imagined defect in appearance. If a slight physical anomaly is present, the person’s concern is markedly excessive.
- B.** The preoccupation causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C.** The preoccupation is not better accounted for by another mental disorder (e.g., dissatisfaction with body shape and size in Anorexia Nervosa [discussed in Chapter 10]).

Source: Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Text Revision, Fourth Edition, (Copyright 2000) American Psychiatric Association.

Body dysmorphic disorder

A somatoform disorder characterized by excessive preoccupation with a perceived defect or defects in appearance.

People with body dysmorphic disorder may compulsively exercise, diet, shop for beauty aids, pick at their skin, try to hide perceived defects, or spend hours looking in the mirror (like Mrs. A., described in Case 8.8, who believed that she had multiple defects). Alternatively, people with body dysmorphic disorder may try to avoid mirrors altogether. The preoccupation with—or attempts to hide—a perceived defect can be difficult to control and therefore devastating, consuming up to 8 hours each day (Phillips, 2001). An individual with body dysmorphic disorder may seek reassurance (“How do I look?”), but any positive effects of reassurance are transient; a half-hour later, the person with body dysmorphic disorder may ask the same question—even of the same person! Unfortunately, these behaviors, which are intended to decrease anxiety about appearance, end up increasing anxiety.

CASE 8.8 ► FROM THE OUTSIDE: Body Dysmorphic Disorder

Ms. A was an attractive 27-year-old single white female who presented with a chief complaint of “I look deformed.” She had been convinced since she was a child that she was ugly, and her mother reported that she had “constantly been in the mirror” since she was a toddler. Ms. A was obsessed with many aspects of her appearance, including her “crooked” ears, “ugly” eyes, “broken out” skin, “huge” nose, and “bushy” facial hair. She estimated that she thought about her appearance for 16 hours a day and checked mirrors for 5 hours a day. She compulsively compared herself with other people, repeatedly sought reassurance about her appearance from her boyfriend and young son, applied and reapplied makeup for hours a day, excessively washed her face, covered her face with her hand, and tweezed and cut her facial hair. As a result of her appearance concerns, she had dropped out of high school and then college. She avoided friends and most social interactions. Ms. A felt chronically suicidal and had attempted suicide twice because, as she stated, “I’m too ugly to go on living.”

(Phillips, 2001, pp. 75–76)

Individuals who have body dysmorphic disorder may feel so self-conscious about a perceived defect that they avoid social situations (American Psychiatric Association, 2000), which results in their having few (or no) friends nor a romantic partner. Some try to get medical or surgical treatment for a “defect,” such as plastic surgery, dental work, or dermatological treatment. But surgery often does not help; in fact, the symptoms of the disorder can actually be worse after surgery (Veale, De Haro, & Lambrou, 2003). In extreme cases, when some people with body dysmorphic disorder can’t find a doctor to perform the treatment they think they need, they may try to do it themselves (so-called D.I.Y., or do-it-yourself, surgery). Table 8.17 presents additional facts about body dysmorphic disorder.

Across cultures, features of body dysmorphic disorder are generally similar. However, *koro*, a condition that is observed in some people in Southeast Asia and that is somewhat similar to body dysmorphic disorder, has unique features: Those

Pop star Michael Jackson’s face changed repeatedly over time, particularly his nose, chin, and cheeks, although he said that he only had surgery on his nose to help his singing. Might Michael Jackson have suffered from body dysmorphic disorder?

Table 8.17 ▶ Body Dysmorphic Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none">• Approximately 0.7–2.3% of the general population has body dysmorphic disorder at any given time (Otto et al., 2001; Phillips, 2001).• Among people having plastic surgery or dermatological treatment, prevalence rates range from 6% to 15% (Phillips, 2001).
Comorbidity
<ul style="list-style-type: none">• Up to 60% of people with body dysmorphic disorder are also depressed; body dysmorphic disorder usually emerges first (Otto et al., 2001; Phillips, 2001).• Thirty-eight percent of people with body dysmorphic disorder may also have social phobia (Coles et al., 2006).• Up to 30% of people with body dysmorphic disorder also have OCD (Phillips, 2001).• In one survey, almost half of those with body dysmorphic disorder had (at the time or previously) a substance-use disorder (Grant et al., 2005).• Almost a third of those with body dysmorphic disorder will also develop an eating disorder (Ruffolo et al., 2006).
Onset
<ul style="list-style-type: none">• Body dysmorphic disorder usually begins in adolescence (Phillips & Diaz, 1997; Phillips, Menard, et al., 2005), but it can go undiagnosed for several years if the person does not discuss the symptoms with anyone.
Course
<ul style="list-style-type: none">• Body dysmorphic disorder is generally chronic, with fewer remissions than depression or most anxiety disorders (Phillips, Pagano et al., 2005, 2006; Phillips, Quinn, & Stout, 2008).• The intensity of symptoms may ebb and flow (Phillips & Diaz, 1997).• Over 25% of adults with body dysmorphic disorder have been housebound for at least 1 week; 8% were unable to work and received disability payments (Albertini & Phillips, 1999; Phillips et al., 1994).• Two surveys found that about 30% of people with body dysmorphic disorder had attempted suicide (Phillips et al., 1994; Phillips, Coles, et al., 2005).
Gender Differences
<ul style="list-style-type: none">• Body dysmorphic disorder affects both genders with approximately equal frequency, but men and women tend to differ with regard to the specific body parts they view as defective (Phillips, Menard, & Fay, 2006): Women are preoccupied with body weight, hips, breasts, and legs, and are more likely to pick their skin compulsively. In contrast, men are preoccupied with body build, genitals, height, excessive body hair, and thinning scalp hair, and are more likely to abuse or be dependent on alcohol.• A variant of body dysmorphic disorder has been documented in some men who use anabolic steroids to build up their perceived weak muscles (Phillips, 2001).
Cultural Differences
<ul style="list-style-type: none">• Generally, symptoms of body dysmorphic disorder are similar across cultures, although certain body attributes may be more likely to be the focus of concern, depending on what physical attributes are valued in a given culture (Pope et al., 1997, 2000).

with koro are preoccupied with their penis (in men) or labia, nipples, or breasts (in women), and fear that those body parts are shrinking or retracting and will disappear into their bodies, possibly resulting in death. In contrast to body dysmorphic disorder, koro is usually brief and symptoms disappear after reassurance.

Diagnosing Body Dysmorphic Disorder Versus Other Disorders

If some of the descriptions of the symptoms of body dysmorphic disorder seem to you to resemble those of anxiety disorders, you’re right. Body dysmorphic

disorder shares some features with anxiety disorders (see Chapter 7): (1) Like phobia disorders (agoraphobia, social phobia, and specific phobias), body dysmorphic disorder can involve an avoidance of anxiety-causing stimuli. (2) Like social phobia, it involves an excessive fear of being evaluated negatively. (3) Like OCD, body dysmorphic disorder involves obsessions (thoughts about a “defect”), as well as highly time-consuming compulsive behaviors. (As noted earlier, hypochondriasis also shares some of these features, although the compulsive behaviors are not usually as time-consuming.)

Because of these similarities and because patients with body dysmorphic disorder are highly anxious about the perceived deficit, some researchers advocate classifying body dysmorphic disorder as an anxiety disorder (Castle & Rossell, 2006; Mayou et al., 2005).

Understanding Body Dysmorphic Disorder

Research on the factors that contribute to body dysmorphic disorder has been limited thus far and has tended to focus on psychological factors. We now examine what is known about those factors as well as neurological and social ones.

Neurological Factors

One hint about the brain systems that underlie body dysmorphic disorder was provided by the tragic case of a young man whose brain became inflamed. This inflammation caused the frontal-temporal portions to atrophy, which in turn led to body dysmorphic disorder (Gabbay et al., 2003). These brain areas are involved in storing new information in memory—and thus abnormalities in them might explain why patients with body dysmorphic disorder have difficulty “updating” their impressions of themselves.

In addition, there is evidence that these patients have impaired functioning of serotonin (Marazziti et al., 1999). People who have anxiety disorders—including OCD—often have low levels of serotonin, and thus this finding is consistent with the idea that body dysmorphic disorder is related to anxiety disorders.

Finally, body dysmorphic disorder may arise, at least in part, from some of the same underlying genetic characteristics that give rise to OCD: When first-degree relatives of OCD patients were studied, many more of them had body dysmorphic disorder than in a comparable control group (Bienvenu et al., 2000). This finding is also consistent with the idea that body dysmorphic disorder is related to anxiety disorders (particularly OCD).

Psychological Factors: Focus on Imperfections

Patients with body dysmorphic disorder exhibit a variety of cognitive biases. Such patients:

- are easily distracted by emotional information, even when the information is unrelated to appearance (Buhlmann et al., 2002).
- tend to focus their attention on isolated body parts and are hypervigilant for any possible bodily imperfections.
- engage in *catastrophic thinking*, believing that such imperfections will lead to dire consequences, such as when a pimple acts as a neon light, calling attention to itself for all to see, which leads observers to think ill of the individual with the pimple (Buhlmann, Etcoff, & Wilhelm, 2008).

Like people with other somatoform disorders, people with body dysmorphic disorder often engage in behaviors that temporarily reduce their anxiety. For example, they might try to avoid mirrors (and possibly people) or develop new ways to hide a “defect”—with painstakingly applied makeup or contrived use of clothing or hats. However, just as avoidance of anxiety-inducing stimuli maintains faulty beliefs in people with phobias, so too with avoidance in body dysmorphic

Mauro Fermariello/Photo Researchers, Inc.

Compared to people with major depressive disorder, those with body dysmorphic disorder are more likely to have an education or job in art or design. However, don't infer causality from this correlation: Although it is possible that being immersed in art or design *causes* body dysmorphic disorder, it is also possible that people preoccupied with their body tend to pursue learning about or working in the arts (Veale, Ennis, & Lambrou, 2002).

disorder: Patients never have an opportunity to test their (irrational) beliefs. Through negative reinforcement, the behavior persists (see Chapters 2 and 7).

Social Factors: Cultural Emphasis on Certain Body Features

Although the features of body dysmorphic disorder are similar across cultures, the specific body parts that are the focus of patients' attention can vary, depending on the bodily attributes that are valued or emphasized in a given culture or subculture. For instance, many men with body dysmorphic disorder in the United States focus on the perception that they have small or inadequate muscles (Pope et al., 1997, 2000), whereas women tend to focus on their hips and weight (Phillips & Diaz, 1997).

Is Somatoform Disorder a Useful Concept?

Some researchers criticize the concept of somatoform disorders as a category (Mayou et al., 2005; Noyes et al., 2008). They point out that other disorders, such as mood and anxiety disorders, can also be accompanied by bodily symptoms, and so the distinction between bodily symptoms in those disorders and those in somatoform disorders is not clear. In fact, medically unexplained symptoms most frequently occur with depression and anxiety disorders (Smith, et al., 2005). Moreover, many cultures reject the concept of somatoform disorders because body and mind are viewed as interrelated; the fact that there is no medical explanation for a bodily symptom is irrelevant (Lee, 1997).

Other researchers point out that different clinicians often decide on different diagnoses for the same patient with somatoform symptoms, making diagnostic reliability a problem (Simon & Gureje, 1999). Moreover, all four somatoform disorders are rare, particularly SD and hypochondriasis, which decreases their diagnostic usefulness for clinicians using the DSM-IV-TR classification system (Creed, 2006; Creed & Barsky, 2004; Gureje, Ustun, & Simon, 1997; Lynch et al., 1999).

Another criticism notes that the relevant neurological, psychological, and social factors are all apt to contribute to many medical disorders (Bradfield, 2006), and that somatoform disorders are not necessarily best conceived of as psychological disorders. The primary symptoms of somatoform disorders are medical, and the fact that some of the other symptoms are psychological does not imply that the disorders themselves are psychological (Sykes, 2006). For instance, psychological factors may contribute to a heart attack, but heart attack is not included among the DSM-IV-TR list of psychological disorders.

Others point out that relying on the existence of medically *unexplained* symptoms—which underlies the diagnostic category of somatoform disorders—may only reflect the present state of knowledge about a particular set of symptoms (Merskey, 2004). That is, “medically unexplained” means “with present techniques, medically unexplained”—not “in principle, forever impossible to explain medically.” With the passage of time, two sorts of developments may lead the category of somatoform disorders to disappear. First, as more becomes known about the factors that contribute to each somatoform disorder, some of them may be moved to other categories, such as anxiety disorders or dissociative disorders. Second, as medical technology and diagnostic techniques improve, some patients who are currently diagnosed with a somatoform disorder may be shown to have an underlying medical problem that explains their symptoms, and thus this category of psychological diagnosis would no longer be appropriate.

Treating Somatoform Disorders

When treating any of the four somatoform disorders (SD, conversion disorder, hypochondriasis, or body dysmorphic disorder), clinicians target neurological, psychological, and social factors—individually or in combination. As we explain below, cognitive-behavioral therapy is generally the treatment of choice for somatoform disorders. Let's examine similarities and differences in treatment for the four disorders.

Targeting Neurological Factors

Medications such as SSRI or St. John's wort may be used to treat some anxiety-related symptoms of somatoform disorders (see Table 8.18). As with anxiety disorders, however, when the medication is stopped, the symptoms usually return. There has not been much rigorous research on this form of treatment for somatoform disorders; the studies that have been reported have rarely included appropriate control groups, such as a placebo group or a wait-list control group to determine whether the disorder spontaneously improves with time. Other type of treatments, such as biofeedback, also target neurological factors (as shown in Table 8.18).

Were Anna O. to be treated by a mental health clinician today, she might receive medication. Anxiety or depression may have contributed to her symptoms, and if medication for these disorders did not alleviate her hallucinations, the clinician might recommend an antipsychotic medication (Martorano, 1984). Note that Anna O. *was* given medications frequently used at that time: morphine (typically given for pain relief) and chloral hydrate (a narcotic used to induce sleep). She became dependent on both of these substances, and after her “talking cure” with Breuer ended, she needed inpatient treatment to end her dependence.

Table 8.18 ▶ Targeting Neurological Factors for Somatoform Disorders

Disorder	Medication	Other Treatment	Comment
Somatization Disorder	SSRI ^a or St. John's Wort ^b	Biofeedback to decrease bodily tension or ECT	Medication studies often do not include appropriate placebo or wait-list control groups.
Conversion Disorder	For pseudoseizures, antianxiety medication (diazepam) ^c	ECT ^d ; biofeedback ^e or TMS ^f for conversion paralysis	There have been very few rigorous medication studies.
Hypochondriasis	For obsessive and compulsive symptoms, an SSRI, particularly fluoxetine ^g		A wide range of medications can lead to improvement, including antipsychotics, ^h antidepressants, and antianxiety drugs, ⁱ suggesting that the specific medication is less important than the placebo effect of taking a medication. ^j Without CBT, relapse is likely when medication is stopped.
Body Dysmorphic Disorder	For obsessive and compulsive symptoms, an SSRI ^k		Without CBT, relapse is likely when medication is stopped. ^l

^aEscobar et al., 1996; ^bMüller et al., 2004; ^cAtaoglu et al., 2003; ^dGiovanoli, 1988; ^eFishbain et al., 1988; ^fSchonfeldt-Lecuona et al., 2003; ^gFallon, 2004; Fallon et al., 1993, 2003; Magarinos et al., 2002; Mayou & Farmer, 2002; Phillips, 2001, Phillips, Albertini, & Rasmussen, 2002; ^hFawcett, 2002; Weintraum & Robinson, 2000; ⁱKjernsted, Enns, & Lander, 2002; Oosterbaan et al., 2001; Stone, 1993; Wesner & Noyes, 1991; ^jFallon et al., 1996; ^kFallon, 2004; Jefferys & Castle, 2003; Magarinos et al., 2002; Mayou & Farmer, 2002; Phillips, Albertini, & Rasmussen, 2002; Phillips & Hollander, 2008; Phillips & Najjar, 2003; ^lPhillips, 2000.

Targeting Psychological Factors: Cognitive-Behavior Therapy

Research suggests that the treatment of choice for most somatoform disorders is cognitive-behavior therapy (CBT). As shown in Table 8.19, the foci of the cognitive and behavioral methods used in treating each of the disorders vary because each disorder has different symptoms. Cognitive methods focus on identifying and then modifying irrational thoughts and shifting attention away from the body and bodily symptoms. Behavioral methods focus on decreasing compulsive behaviors and avoidance.

Targeting Social Factors: Support and Family Education

Patients with a somatoform disorder can be helped, in part, merely by feeling that someone understands the pain and distress they feel (Looper & Kirmayer, 2002). For SD and conversion disorder, the therapist strives to understand the context of the symptoms and of their emergence and the way the symptoms affect the patient's interactions with others (Holder-Perkins & Wise, 2001); with these two disorders, treatment may focus on helping the patient communicate more assertively—which can help to relieve the social stressors that contribute to the disorders.

Table 8.19 ▶ Cognitive-Behavior Therapy for Somatoform Disorders

Disorder	Cognitive Focus	Behavioral Focus	Comment
Somatization Disorder	Psychoeducation; cognitive restructuring to modify faulty or irrational beliefs about bodily sensations; teach patients not to amplify the sensations	Identify and then decrease avoidant behaviors, sensations, and activities that lead to physical or psychological discomfort or restriction of activities ^a ; relaxation to decrease physical tension	CBT is generally the most effective treatment for somatization disorder. ^b
Conversion Disorder	Psychoeducation; identify stressors or conflicts associated with the emergence of symptoms; develop alternative ways to resolve the conflict or cope with stressors (problem solving) ^c	Assertiveness training as appropriate; use paradoxical intention (suggesting that the patient continue to have the symptom) to decrease symptoms, as appropriate ^d	Insight-oriented treatment is sometimes used to help patients with conversion disorder understand the meaning of the symptoms. Once the meaning is understood, the symptoms may improve spontaneously. ^e
Hypochondriasis	Identify and modify faulty or irrational beliefs about health worries and bodily sensations (cognitive restructuring); teach patients not to amplify these sensations; decrease catastrophic attributions about sensations and illness worries	Identify sensations and activities that lead to discomfort; identify avoidant behaviors and decrease avoidance; use exposure with response prevention for compulsive behaviors such as bodily checking, seeking reassurance, or visiting doctors frequently	CBT is the most effective treatment for hypochondriasis. ^f Pilot studies have adapted IPT to treat hypochondriasis, and initial results are promising. ^g
Body Dysmorphic Disorder	Psychoeducation; identify and modify irrational body-related thoughts (cognitive restructuring); teach patients to shift attention away from body	Exposure with response prevention for compulsive bodily checking; exposure or systematic desensitization for body areas that are viewed as defective	Behavioral techniques are similar to those used to treat OCD. CBT is the treatment of choice for body dysmorphic disorder. ^h

^aMayou & Farmer, 2002; O'Malley et al., 1999; ^bAllen et al., 2006; Bass, Peveler, & House, 2001; ^cMaldonado & Spiegel, 2001; ^dAtaoglu et al., 2003; ^eMaldonado & Spiegel, 2001; ^fBarsky & Ahern, 2004; Taylor, Asmundson, & Coons, 2005; Wattar et al., 2005; ^gStuart & Noyes, 2005; Stuart et al., 2008; ^hWilliams, Hadjistavropoulos, & Sharpe, 2006.

Treatment may also focus on the family—educating family members about the disorder and the ways they may have inadvertently contributed to or reinforced the patient's symptoms. The therapist may teach family members how to reinforce positive change and to extinguish behavior related to the symptoms (Looper &

Perhaps the most effective treatment for leg paralysis due to conversion disorder may be the simplest: Educate the patient about the nature of the symptoms. At least for three patients in one study, simply showing them their normal test results and contradictions from their physical exam did the trick. These patients walked out of the hospital unaided immediately after these results were given to them (Letonoff, Williams & Didhu, 2002).

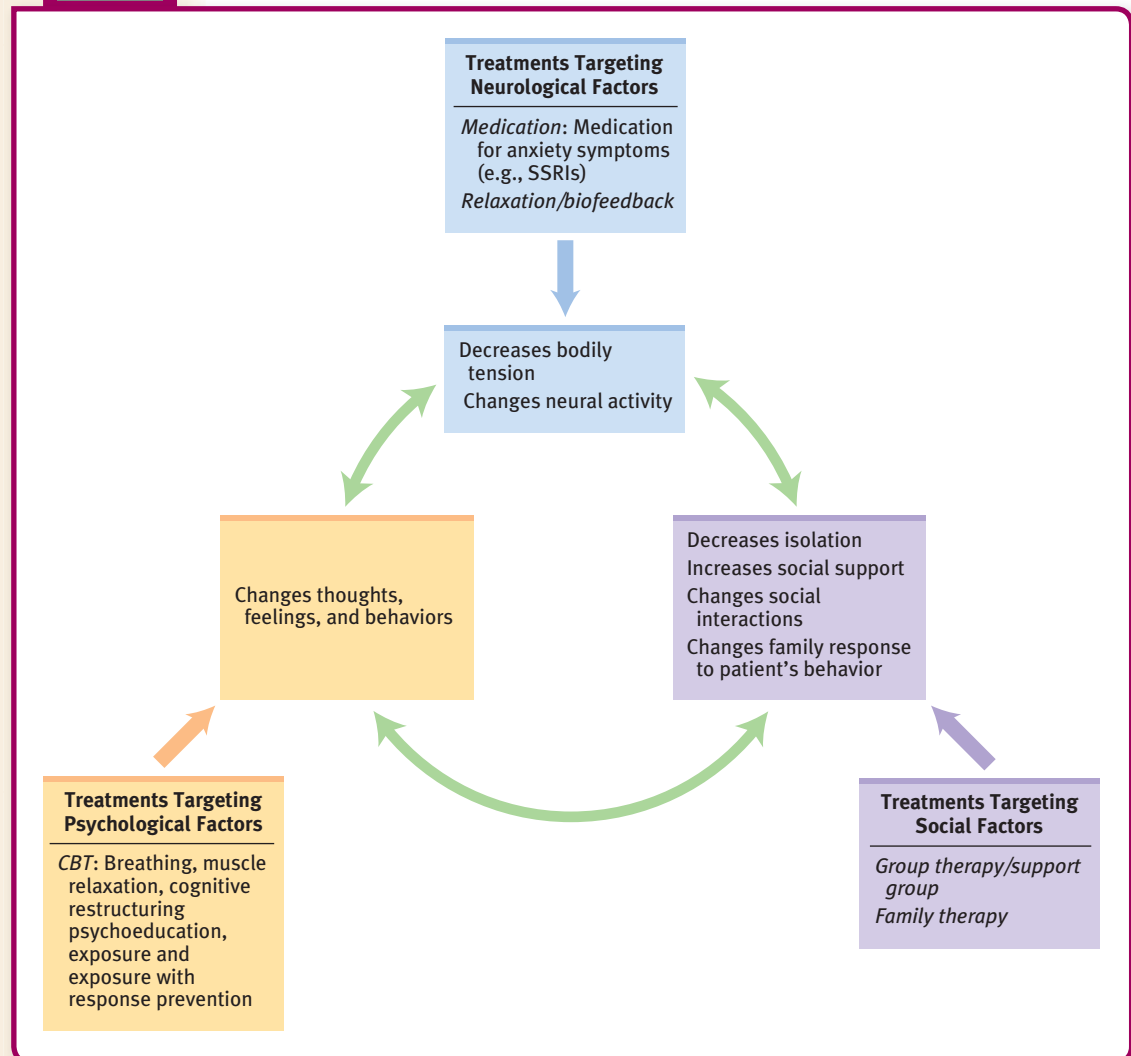

Kirmayer, 2002; Maldonado & Spiegel, 2001). For instance, with SD, family members may be asked *not* to inquire about the patient's bodily symptoms. In addition, support groups may help patients feel less alone and isolated (Looper & Kirmayer, 2002).

FEEDBACK LOOPS IN TREATMENT: **Somatoform Disorders**

Although biofeedback and medication primarily target neurological factors, such techniques can in turn affect the type and quality of attention paid to bodily sensations, and can change the meaning made of bodily sensations (psychological factors). CBT can provide new skills and ways of interpreting the sensations and modifying the preoccupying thoughts, which in turn can decrease the bodily symptoms (neurological factor) and the attention paid to them (psychological factor). Similarly, the relationship with a therapist (social factor) can provide reassurance and support, and as family members change how they respond to the patient's symptoms (social factor), positive change can be enhanced. Figure 8.6 shows how successful treatment of somatoform disorders affects the different types of factors directly and through their feedback loops.

Figure 8.6

Key Concepts and Facts About Somatoform Disorders

- Somatoform disorders involve complaints about physical well-being that cannot be entirely explained by a medical condition, substance use, or another psychological disorder and that cause significant distress or impair functioning. Diagnosing one of these disorders may require many medical tests or visits to physicians to ensure that the physical symptoms are not a result of a medical condition. Somatoform disorders are rare and are most likely to be observed in medical settings. All somatoform disorders involve bodily preoccupation, symptom amplification, and dissociation.
- Somatization disorder (SD) is characterized by multiple specific physical symptoms that are medically unexplained and impair an individual's ability to function. People with SD may avoid activities associated with their symptoms, which can create a vicious cycle as they become out of shape physically.
- The DSM-IV-TR criteria for diagnosing SD have been criticized on several grounds: (1) all symptoms are counted equally; (2) the minimum number of symptoms required is not based on research results; (3) patients' beliefs about their symptoms are not part of the criteria; and (4) the bodily symptoms may be better explained by other psychological disorders.
- Factors that contribute to SD include genes, catastrophic thinking about illness (along with symptom amplification and bodily preoccupation), other people's responses to illness, and the way symptoms function as a means of expressing helplessness.
- Conversion disorder involves sensory and motor symptoms that may initially appear to have neurological causes but in fact are not explained by a medical condition and are not consciously produced. There are three types of symptoms: motor symptoms, sensory symptoms, and seizures.
- Criticisms of DSM-IV-TR diagnostic criteria for conversion disorder include: (1) the prominent role of dissociation suggests that the disorder may be better grouped with dissociative disorders; and (2) many cases of conversion disorder may be a type of factitious disorder.
- Factors thought to contribute to conversion disorder include abnormal functioning of brain areas that interpret and manage other brain areas that process sensation and pain, self-hypnosis and dissociation, and intense social stressors.
- Hypochondriasis is characterized by misinterpretation of bodily sensations and symptoms, which leads to a belief that the individual has a serious illness—this despite no evidence of a medical problem and reassurance from health care personnel. Hypochondriasis has numerous features that are similar to those of anxiety disorders, including compulsions, obsessions, anxiety, and avoidance.
- The neural basis of hypochondriasis shares much with the neural basis of OCD and panic disorder (particularly the latter), but hypochondriasis has at least some distinct neural events. Parts of the brain involved in attention are more activated than normal, at least in certain circumstances.
- Psychological factors that contribute to hypochondriasis include attentional biases and catastrophic thinking (along with symptom amplification and bodily preoccupation).
- Body dysmorphic disorder is characterized by an excessive preoccupation with a perceived defect in appearance, which is either imagined or slight. Body dysmorphic disorder shares features with various anxiety disorders: a fear of being evaluated, obsessions (about a perceived defect), time-consuming compulsive behaviors (to hide or compensate for a perceived defect in some way), and avoidance of anxiety-inducing stimuli or situations. Some researchers advocate reclassifying body dysmorphic disorder as an anxiety disorder.
- Research on body dysmorphic disorder has focused on psychological factors, particularly cognitive biases and catastrophic thinking (along with symptom amplification and bodily preoccupation). A patient's perceived defect tends to be related to bodily attributes that are highly valued in his or her culture or subculture.
- CBT is generally the treatment of choice for somatoform disorders; medications, when used, target anxiety-related symptoms. Group and family therapy are generally used as supplementary treatments.

Making a Diagnosis

- Reread Case 8.5 about Edward, and determine whether or not his symptoms meet the criteria for somatization disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 8.6 about Mary, and determine whether or not her symptoms meet the criteria for conversion disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 8.7 about the unnamed woman, and determine whether or not her symptoms meet the criteria for hypochondriasis. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?
- Reread Case 8.8 about Ms. A, and determine whether or not her symptoms meet the criteria for body dysmorphic disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Jewish Museum, Frankfurt am Main, Germany

Despite Breuer's poor prognosis for Anna's future, she went on to live a full life, becoming an accomplished advocate for and benefactor of poor women and children. In Anna's time, having a psychological disorder was neither a personal disaster nor a signal that life had to become constrained and unrewarding. This is still the case.

Follow-up on Anna O.

Anna O.'s symptoms do not fit neatly into any of the disorders discussed in this chapter. She had hallucinations and dissociative and bodily symptoms, but they probably wouldn't meet the diagnostic criteria for somatization disorder. Today, she would probably be diagnosed with more than one disorder.

Anna's symptoms cleared up near the end of her treatment with Breuer. However, after their final session, she had a major relapse, and Breuer refused to continue to treat her. He found the therapy sessions with Anna too time- and energy-consuming, and, given her relapse, he was not optimistic about her prognosis.

Anna's history for the 6 years after her treatment with Breuer remains largely unknown, although we do know that she was hospitalized several times, some of which were for her dependence on morphine and chloral hydrate, which Breuer had prescribed for her. Despite Breuer's negative prognosis, Anna O. went on to accomplish great things. Her real name was Bertha Pappenheim, and she became a social worker, the director of an orphanage, and the founder of a home for unwed mothers that was dedicated to teaching the women skills to support themselves and their children. For the rest of her life, she strove to improve the lives of poor women and children (Freeman, 1990).

SUMMING UP

Summary of Dissociative Disorders

Dissociation involves a separation of mental processes that are normally integrated—a dissociation of perception, consciousness, memory or identity. To qualify as a dissociative disorder, this separation must cause significant distress or impair functioning. Specific symptoms of dissociative disorders include amnesia, identity problems, derealization, and depersonalization. Dissociative disorders are rare and often may arise in response to traumatic events.

Dissociative amnesia is characterized by significantly impaired memory for important experiences or personal information that cannot be explained as ordinary forgetfulness or accounted for by another psychological disorder, substance use, or a medical condition. Dissociative amnesia most often occurs after some traumatic event. The amnesia may spontaneously disappear, particularly after the person leaves the traumatic situation.

Dissociative fugue is characterized by sudden, unplanned travel and difficulty remembering the past, which in turn leads to identity

confusion. Apparently, the frontal lobes of patients with this disorder are not as effective at accessing stored memories, particularly about the self. Not much is known about the factors that contribute to dissociative fugue; what is known is that people who have had this disorder are more hypnotizable and dissociate more easily than do others.

Depersonalization disorder is characterized by the persistent feeling of being detached from oneself, which may be accompanied by derealization. This disorder appears to involve an under-reaction to emotional stimuli, and is more common among people who experienced severe chronic emotional abuse during childhood than among people who did not have this experience.

Dissociative identity disorder (DID) hinges on the presence of two or more distinct alters, each of which takes turns controlling the person's behavior; some alters seem to be unaware of the existence of other alters. The DSM-IV-TR diagnostic for DID criteria have been criticized for being vague and the symptoms are easy to fake. Although neuroimaging studies of patients with DID find that their brains function differently when

different alters are dominant, such studies have not generally used appropriate control groups. People with this disorder are more hypnotizable and dissociate more readily than do people who do not have this disorder. The diagnosis of DID is controversial.

The posttraumatic model proposes that DID is caused by severe, chronic physical abuse during childhood, which leads to dissociation during the abuse; the dissociated states come to constitute alters, with their own memories and personality traits. The sociocognitive model proposes that DID arises as the result of interactions between a therapist and a suggestible patient, in which the therapist inadvertently encourages the patient to behave in ways consistent with the diagnosis. Both interpretations are consistent with the finding that severe childhood trauma is associated with the disorder.

The goal of treatment for DID, and for dissociative disorders in general, ultimately is to reduce the symptoms themselves and to lower the stress they induce; hypnosis may be used to help integrate dissociated perceptions and memories. According to the posttraumatic model, therapists should help patients,

perhaps through hypnosis, to characterize each alter in detail. In contrast, according to the sociocognitive model, therapists should try to extinguish patients' behaviors related to alters.

Thinking like a clinician

How do mental health clinicians decide whether an individual's dissociative symptoms are normal or abnormal? Which of the two theories of DID do you think is most accurate and why?

The news reports that a 17-year-old boy murdered his stepfather. The boy says that his stepfather brutally abused him as a child, and local medical and emergency room records indicate numerous "accidents" that were consistent with such abuse. The boy also says that he has no memory of killing his stepfather; his defense attorney and several psychiatrists claim that the boy has DID and that an alter killed the stepfather. Based on what you have read in this chapter, how might this boy have developed this disorder? (Mention neurological, psychological, and social factors and possible feedback loops.) What would be appropriate treatments for him and why? Do think it is fair to punish a patient with DID for what an alter did? Why or why not?

Summary of Somatoform Disorders

Somatoform disorders involve complaints about physical well-being that cannot be entirely explained by a medical condition, substance use, or another psychological disorder and that cause significant distress or impair functioning. All somatoform disorders involve bodily preoccupation, symptom amplification, and dissociation.

Somatization disorder (SD) is characterized by multiple specific physical symptoms that are medically unexplained and impair an individual's ability to function. People with SD may avoid activities associated with their symptoms, which can create a vicious cycle as they become out of shape physically. Factors that contribute to SD include genes, catastrophic thinking about illness (along with symptom amplification and bodily preoccupation), other people's responses to illness, and the way symptoms function as a means to express helplessness.

Conversion disorder is characterized by sensory and motor symptoms, and seizures, which may initially appear to have neurologi-

cal causes but in fact are not explained by a medical condition and are not consciously produced. Factors thought to contribute to conversion disorder include abnormal functioning of brain areas that process sensation and pain, self-hypnosis and dissociation, and intense social stressors.

Hypochondriasis is characterized by misinterpretation of bodily sensations and symptoms, which leads to a belief that the individual has a serious illness—this despite no evidence of a medical problem and reassurance from health care personnel. Hypochondriasis has numerous features that are similar to those of anxiety disorders, including compulsions, obsessions, anxiety, and avoidance; with hypochondriasis, the anxiety is focused on health-related matters.

The neural basis of hypochondriasis shares much with the neural basis of OCD and panic disorder, but the three disorders arise from at least some distinct neural events. Psychological factors that contribute to hypochondriasis include attentional biases and catastrophic thinking, along with symptom amplification and bodily preoccupation.

Body dysmorphic disorder is characterized by an excessive preoccupation with a perceived defect in appearance, which is either imagined or slight. Body dysmorphic disorder shares features with various anxiety disorders: a fear of being evaluated, obsessions (about a perceived defect), time-consuming compulsive behaviors to hide or compensate for a perceived defect in some way, and avoidance of anxiety-inducing stimuli or situations. Some researchers advocate reclassifying body dysmorphic disorder as an anxiety disorder.

CBT is generally the treatment of choice for somatoform disorders; medications, when used, target anxiety-related symptoms. Group and family therapy are generally used as supplementary treatments.

Thinking like a clinician

What do the four somatoform disorders have in common? What do body dysmorphic disorder and hypochondriasis—and not the other two somatoform disorders—have in common? Why might conversion disorder more appropriately be classified as a dissociative disorder? Do you think it should be—why or why not?

Now 57 years old, Mr. Andre left his native Haiti 5 years ago and moved to the United States. Unemployment rates in the U.S. were high at the time of his arrival and Mr. Andre

had a hard time getting a job; he felt that he was being discriminated against. His wife supported the family for 2 years by cleaning homes. After 2 years of looking, Mr. Andre did get a job, delivering sandwiches to offices at lunchtime. Within 4 months of starting this job, though, he fell down a flight of stairs after making a delivery, and he has had persistent lower back pain since, leaving him bedridden and unable to work. Doctors have not found a medical explanation for this pain. What factors should (and shouldn't) clinicians take into account when evaluating Mr. Andre for a somatoform disorder? If they do think he has such a disorder, which one do you think it might be and why, and what treatment(s) should be recommended to Mr. Andre if you are correct? On what basis could some of the somatoform disorders be ruled out?

Substance Use Disorders

The musical group the Beatles formed in 1957 and soared to international acclaim in 1963. The band's celebrity was so great that the four members—John Lennon, Paul McCartney, George Harrison, and Ringo Starr—found that they were essentially prisoners in their hotel rooms when on tour. Frenzied fans would try to steal into the rooms, going so far as to lower themselves down from the hotel roof! At Beatles' concerts, fans screamed so loudly that the band members could not hear themselves sing and play over the din. Sick of it all, the Beatles stopped touring in 1966 and just recorded music in the studio. Many of their songs broke all of the conventions of rock-and-roll music, and the Beatles developed the first themed rock album with *Sgt. Pepper's Lonely Hearts Club Band*. The album practically reeked of drug use and the band members then became famous both for their music and for their lifestyles—setting a model for a generation that experimented with mind-altering drugs. By 1968, however, tensions among the four band members had become severe, and they reached the breaking point in 1970, when the group officially dissolved. Beneath the musical history of the Beatles is a story of substance use, abuse, and dependence that illustrates the focus of this chapter.

Substance Use, Abuse, and Dependence

The Beatles used some drugs because that was what their peers did. For instance, almost all boys—and some girls—their age growing up in Liverpool, England smoked cigarettes. It was simply what was done. Similarly, the young band members drank alcohol; again, doing so was the norm. Sometimes they used a drug specifically for the effect it brought, such as when they took “uppers” (stimulants) to stay awake when performing late at night. When they toured in the early 1960s, they took drugs to relieve the monotony of life on the road; they would swallow a pill, “just to see what would happen” (Norman, 1997, p. 244). A few years later, they took “acid” (LSD) to help them understand the meaning of life and attain enlightenment and peace.

- Targeting Neurological Factors
- Targeting Psychological Factors
- Targeting Social Factors
- Feedback Loops in Treatment:
- Substance Use Disorders

Psychoactive substance

A chemical that alters mental ability, mood, or behavior.

Substance use disorders

Psychological disorders characterized by abuse of or dependence on psychoactive substances.

Substance intoxication

The reversible dysfunctional effects on thoughts, feelings, and behavior that arise from the use of a psychoactive substance.

All four members of the Beatles tried various psychoactive substances. A **psychoactive substance** is a chemical that alters mental ability, mood, or behavior. Psychoactive substances, commonly referred to as *drugs*, can be used for therapeutic purposes (for example, taking an antidepressant to diminish symptoms of depression), for nontherapeutic purposes (for example, drinking an alcoholic beverage to “unwind”), and for intoxication (for example, using a drug to get “wasted”). Frequent use of a psychoactive substance can proceed to abuse or dependence.

According to DSM-IV-TR, **substance use disorders** are characterized by abuse of or dependence on psychoactive substances. With substance use disorders, the psychoactive substance is taken either because of its effect on mood, behavior, or cognition or because it prevents uncomfortable withdrawal symptoms (American Psychiatric Association, 2000).

Why does a book on abnormal psychology include a discussion of substance use? For three reasons: First, when such use leads to abuse, it disrupts the individual’s normal functioning. Substance abuse can lead to decidedly abnormal cognition or affect; not only can certain drugs produce delusions and hallucinations, but they can also induce paranoia and fear. Second, when a person becomes drug dependent, he or she may desire the substance to the point that the usual balance of motivations becomes skewed. He or she may forgo eating, sex, productive work, and all the other things that make life worth living in order to obtain the drug. Third, drug abuse may help to trigger various psychological disorders or exacerbate symptoms of a comorbid disorder. For instance, as we’ll see, drug abuse is often comorbid with depression and other psychological disorders. In short, chronic substance abuse can have a ripple effect on a user’s life, leading to impaired functioning in work, school, and relationships.

Is simply the act of trying a drug enough to meet the criteria for having a substance use disorder? What’s the difference between use and abuse or between abuse and dependence? Moreover, does the context matter—does where and why someone uses a drug affect whether he or she would be diagnosed as abusing it? The answers to these questions help to determine whether drug use meets the criteria for a disorder and help to make decisions about treatment. Let’s examine the differences among intoxication, use, abuse, and dependence.

Substance Use Versus Intoxication

The Beatles, individually and collectively, experimented with numerous drugs. Paul McCartney is generally described as having been the most cautious about drugs, whereas John Lennon used them regularly, sometimes continually. Lennon confessed to being “a drunk” in art school, and he began taking “pills” (stimulants) at age 17, when he became a musician. Why pills? “The only way to survive in Hamburg [Germany, where the band played at various periods in 1961, 1962, and 1963], to play eight hours a night, was to take pills. The waiters gave you them—the pills and drink” (Wenner, 1971). Lennon recounted how, during the filming of the Beatles’ second movie, *Help!*, he and his bandmates

turned on to pot, and we dropped drink, simple as that. I’ve always needed a drug to survive. The others, too, but I always had more, more pills, more of everything because I’m more crazy probably.

(Wenner, 1971)

At one time or another, each Beatle could have been diagnosed with **substance intoxication**: reversible dysfunctional effects on thoughts, feelings, and behavior that arise from the ingestion of a psychoactive substance (see Table 9.1). The specific effects of substance intoxication depend on the substance and whether a person uses it only occasionally (getting drunk on Saturday night) or chronically (drinking to excess every night).

In contrast to substance intoxication, *substance use* is a general term that indicates simply that a person has used a substance—via smoking, swallowing, snorting, injecting it, or otherwise absorbing it. This term does not indicate the extent or effect of the exposure to the substance.

Table 9.1 ▶ DSM-IV-TR Criteria for Substance Intoxication

- The development of a reversible substance-specific syndrome that arises from the recent ingestion of (or exposure to) a substance.

Note: Different substances may produce similar or identical syndromes.

- The clinically significant maladaptive behavioral or psychological changes associated with intoxication (such as belligerence, rapidly changing mood, cognitive impairment, impaired judgment, impaired social or occupational functioning) are due to the direct physiological effects of the substance on the central nervous system and develop during or shortly after use of the substance.

Substance Abuse and Dependence

The Beatles used stimulants nightly when performing in Germany, but does that mean they were abusing the drugs? Were they dependent on the pills? Were they addicted? Some mental health clinicians and researchers avoid using the term *addiction*, partly because of its negative moral connotations and partly because the term is less exact than *abuse* or *dependence*. Moreover, *addiction* has been applied to other objects or behaviors such as chocolate, work, sex, love, and Internet use—which obscures its meaning. However, other clinicians and researchers believe that the upcoming revision of the DSM (DSM-V) should incorporate the term addiction in its classification system (O'Brien, Volkow, & Li, 2006). Those clinicians and researchers define *addiction* as the compulsion to seek and then use a psychoactive substance either for its pleasurable effects or, with continued use, for relief from negative emotions such as anxiety or sadness. These compulsive behaviors persist, despite negative consequences (National Institute on Drug Abuse [NIDA], 2007g).

Like this definition of addiction, the DSM-IV-TR definition of substance abuse focuses on the behaviors related to obtaining and using a drug, as well as the consequences of that use. According to DSM-IV-TR, **substance abuse** is a pattern of harmful use of a psychoactive substance that leads to harm or other adverse effects; see Table 9.2 (American Psychiatric Association, 1994, 2000). Whereas *intoxication* refers to the direct results of using a substance, *substance abuse* focuses more on the indirect effects of repeated use, such as legal problems, unmet obligations, or reckless behavior while using the substance (for instance, driving while under the influence). Although occasional illegal use of a substance may be associated with medical, legal, and psychological risks, it does not necessarily constitute *substance abuse* according to DSM-IV-TR. Consider someone who takes a stimulant such as Ritalin to stay awake only when cramming for exams during finals. Although such use could create medical, social, legal, or occupational problems, unless problems do arise and meet the criteria in Table 9.2, the use would not be considered abuse.

Use or abuse of a psychoactive substance can lead to **substance dependence**, the pattern of persistent and compulsive use of a psychoactive substance, despite its negative effects on work, relationships, health, or its legal consequences; Table 9.3 lists the specific DSM-IV-TR diagnostic criteria. Note that the criteria for substance abuse refer to the indirect effects of repeatedly using the substance—such as legal or social problems—whereas many of the criteria for substance dependence refer to the direct effects of compulsive and repeated substance use. According to DSM-IV-TR, patients cannot be diagnosed with both substance abuse and substance dependence; patients who meet the criteria for both disorders are only diagnosed with substance dependence.

Table 9.2 ▶ DSM-IV-TR Diagnostic Criteria for Substance Abuse

A. A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) of the following, occurring within a 12-month period:

- (1) recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)
- (2) recurrent substance use in situations in which it is physically hazardous to use the substance (e.g., driving an automobile or operating a machine when impaired by substance use)
- (3) recurrent substance-related legal problems (e.g., arrests for substance-related disorderly conduct)
- (4) continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights).

Source: Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Text Revision, Fourth Edition, (Copyright 2000) American Psychiatric Association.

DSM-IV-TR uses the terms *abuse* and *dependence* rather than *addiction*, in part because the word *addiction* has been overused. However, *abuse* and *dependence* may come to be similarly overused.

Substance abuse

A pattern of use of a psychoactive substance that leads to harm or other adverse effects.

Substance dependence

The persistent and compulsive use of a psychoactive substance, despite its negative effects on work, relationships, health, or its legal consequences.

Table 9.3 ▶ DSM-IV-TR Diagnostic Criteria for Substance Dependence

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

- (1) Tolerance, as defined by either of the following:
 - (a) a need for markedly increased amounts of the substance to achieve intoxication or desired effect
 - (b) markedly diminished effect with continued use of the same amount of the substance
- (2) Withdrawal, as manifested by either of the following:
 - (a) the characteristic withdrawal syndrome for the substance
 - (b) the same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms
- (3) The substance is often taken in larger amounts or over a longer period than was intended
- (4) There is a persistent desire or unsuccessful efforts to cut down or control substance use
- (5) A great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use the substance (e.g., chain-smoking), or recover from its effects
- (6) Important social, occupational, or recreational activities are given up or reduced because of substance use
- (7) The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption).

Figure 9.1

Note: BCR stands for “body’s compensatory response.”

9.1 ▶ Tolerance and Withdrawal

Using a see-saw as a metaphor for the body’s response to repeated drug use, this figure illustrates the progression to tolerance and withdrawal: (a) no drug use; (b) an imbalance arises from drug use; (c) the brain and body adapt to the drug, and tolerance begins; (d) more of the drug is taken to overcome tolerance; (e) the brain and body adapt to this higher level of drug use; (f) because of the adaptation, when drug use is discontinued (or reduced) that adaptation creates withdrawal symptoms.

Source: Adapted from Goldstein, 1994.

Two neurologically based symptoms of substance dependence can contribute to the diagnosis: *tolerance* and *withdrawal* (American Psychiatric Association, 2000). **Tolerance** occurs when, with repeated use, more of the substance is required to obtain the same effect (e.g., intoxication). For instance, someone who drinks alcohol regularly is likely to develop tolerance to alcohol and find that it takes more drinks to obtain a “buzz” and even more drinks to get drunk. As shown in Figure 9.1, with regular use of alcohol and some drugs, the body adapts and tries to compensate for the repeated influx of the substance.

Withdrawal refers to the set of symptoms that arises when a regular user decreases intake of the substance. As shown in Figure 9.1f, withdrawal arises because the body has compensated for the repeated

influx of a drug and, when the person stops taking the drug, the neurological compensatory mechanisms are still in place, but the drug is no longer there to counterbalance them. Unfortunately, withdrawal symptoms can make it difficult for habitual users of some substances to cut back or stop their use: As they cut back, they may experience uncomfortable or even life-threatening symptoms that are temporarily alleviated by resuming use of the substance.

In most cases, substances that can lead to tolerance with regular use are also likely to produce withdrawal symptoms if stopped or taken at lower doses. There are some exceptions—substances for which tolerance may develop but withdrawal symptoms do not arise. For example, this is the case with LSD (lysergic acid diethylamide, a hallucinogen). In contrast, chronic marijuana use can lead to withdrawal symptoms, but the individual may not necessarily experience tolerance. Regular use of other substances, such as PCP (phencyclidine), causes neither tolerance nor withdrawal, and a diagnosis of dependence on this drug relies on other symptoms.

Use Becomes Abuse

People can develop substance abuse in three general ways. First, substance abuse can arise unintentionally, as can occur through environmental exposure. Consider a gas station attendant who daily inhales gasoline fumes.

Second, substance abuse (or dependence) can develop when the psychoactive element is a side effect, and the substance is taken for medicinal reasons unrelated to the psychoactive effect. For instance, former Chief Justice of the Supreme Court, William Rehnquist began taking the sedative-hypnotic drug *ethchlorvynol* (Placidyl) for insomnia and pain after back surgery in 1971 (Cooperman, 2007). Ten years later, it was clear to many that something was wrong: Rehnquist had become dependent on the drug, taking it in very large doses because he had developed a tolerance for it. In fact, the dose was so large that it impaired his speech. When he was abruptly taken off the medication, his withdrawal symptoms included paranoia and hallucinations; he was then put back on the medication and his use was gradually reduced (Mauro, 2007).

Third, substance abuse can develop as a result of the intentional use of a substance for its psychoactive effect, as the Beatles did when they took the stimulant Preludin during their nightly 8-hour gigs in Hamburg. The drug's stimulant properties gave them energy to perform these grueling sets (Spitz, 2005). In this third path toward substance abuse and dependence, someone may know the risks in using the substance but nonetheless underestimate his or her own level of risk (Weinstein, 1984, 1993). It is this third path toward developing substance abuse that has been the target of most research, and a number of different theories have tried to explain this type of slide from use to abuse.

Common Liabilities Model

The **common liabilities model** (also called the *problem behavior theory*; Donovan & Jessor, 1985) was developed in response to the results from a study that followed students from grades 7–9 into adulthood; the researchers found that adolescents who later developed substance abuse were likely to exhibit “problem behaviors” such as drug and alcohol use, early sexual intercourse, and delinquent behaviors (e.g., stealing and gambling). The researchers proposed that these various problem behaviors may stem from the same underlying factors—that is, the adolescents had *common liabilities*, related to neurological, psychological, or social factors or to feedback loops among these factors—hence the name given to this approach to understanding how use becomes abuse or dependence. Subsequent studies have supported this explanation (Agrawal et al., 2004; Ellickson et al., 2004).

Tolerance

The physiological response that arises from repeated use of a substance such that more of it is required to obtain the same effect.

Withdrawal

The set of symptoms that arises when a regular user decreases or stops intake of an abused substance.

Common liabilities model

The model that explains how neurological, psychological, and social factors make a person vulnerable to a variety of problematic behaviors, including substance abuse and dependence; also called *problem behavior theory*.

Substance use can become abuse in different ways, illustrated here left to right: through environmental exposure; when the psychoactive component is a side effect of a medication taken for medicinal purposes; or when people set out to use a substance for its psychoactive effects.

moodboard/Corbis

Punchstock/BananaStock

Chuck Savage/Corbis

One particularly important common liability is a problem with impulsivity—especially with difficulty restraining urges to engage in potentially harmful behaviors. Substance use disorders are not the only type of disorders that arise, in part, from problems with impulsivity. A variety of DSM-IV-TR disorders are characterized by impulsivity, including obsessive-compulsive disorder and the eating disorder, bulimia nervosa. In fact, DSM-IV-TR includes a separate category of impulse-control disorders that are not included in other categories. Such disorders involve compulsive or impulsive behaviors such as stealing (kleptomania), lighting fires (pyromania), and gambling, among others. Common liabilities may account for the high comorbidity between substance use disorders and these impulse-control disorders.

Gateway Hypothesis

Another theory that researchers have used to explain the progression from use to abuse or dependence is the gateway hypothesis, and the related *stage theory* (Kandel, 2002; Kandel & Logan, 1984). According to the **gateway hypothesis**, “entry” drugs such as cigarettes and alcohol serve as a gateway to (or the first stage in a progression to) use of “harder” drugs, such as cocaine, or illegal use of prescription medication. Researchers have found that some, though not all, adolescent users of entry drugs did go on to use marijuana (White et al., 2007), and some of these marijuana users moved on to harder drugs. Researchers have found that such adolescents usually first use tobacco, beer, or wine, and then progress to use marijuana and hard liquor (Kandel, 2002; Kandel &

Logan, 1984). Teens are unlikely to experiment with marijuana unless they first experimented with legal—but restricted—substances such as alcohol. Similarly, adolescents and young adults don’t generally try other illegal substances without having used marijuana (see Figure 9.2). The gateway hypothesis illuminates cases like that of Butch Jamieson (Case 9.1): He began with alcohol, moved on to marijuana, and then to heroin.

Figure 9.2

9.2 ▶ Stages of Drug Use

CASE 9.1 ▶ FROM THE INSIDE: Progression from Alcohol to Heroin Dependence

My name is Butch Jamieson. This is my story. At this point in my life I have been clean 29 and a half years; before this I drank and used drugs for 23 years of my life. My first experience with any type of drug was alcohol at the tender age of 5. I stole some wine my mother was saving for some friends. I got extremely sick after drinking the whole bottle. From this point on I would look for the chance to steal drinks that were left behind after my parents would have people over for drinks. Everyone in my family drank, so I thought that this was normal behavior. My father had problems with drinking and he died when I was 15 years old as a result of his drinking; nine years later my mother died from the same thing. This did not tell me anything at all.

At age ten or 11, we moved to SE Washington DC where my drinking took off. At that time we did not get into the other drugs, because the older guys would not give it to us. A short time passed and this would soon change; the year was 1970, and pot was the big thing in town. We soon started to smoke pot and drink, and then at 21 years of age I allowed a sixteen year old boy to stick a needle in my arm and then my heroin addiction started. . . . Jails, Psych wards, OD-ing a few times did not stop me.

Source: Faces and Voices of Recovery, 2007a.

Gateway hypothesis

The proposal that use can become abuse when “entry” drugs serve as a gateway to (or the first stage in a progression to) use of “harder” drugs.

This general pattern of progression has been found in various countries and among different ethnic groups (Kandel & Yamaguchi, 1985). With any type of drug, there is also a typical progression of stages of use: initiation, experimentation, casual use, regular use, abuse, and dependence (Clayton, 1992; Werch & Anzalone, 1995). However, experimenting with drugs does not necessarily mean that an individual will march through this sequence to the end. Many people stop at one of the earlier stages, and most people who use entry drugs do not go on to develop substance

abuse or dependence. The gateway hypothesis is not a blueprint for all users; rather, it is a way to understand how people who abuse substances come to end up in that situation. In addition, even when people do come to abuse drugs or be dependent on them, they do not necessarily go through the specified sequence. In fact, some people with substance abuse problems had a reverse pathway: They started using harder drugs before softer ones (George & Moselhy, 2005), for example, using marijuana before using tobacco (Humfleet & Haas, 2004).

Factors Associated With Progressing from Entry Drugs to Hard Drugs

Two factors are associated with progressing from using entry drugs to using hard drugs:

1. **Age.** The younger a person is when he or she starts to use drugs or alcohol, the more likely he or she will be to abuse drugs later in life—and the less likely to decrease drug use or stop abusing drugs (D’Amico et al., 2001; Ginzler et al., 2003; Kandel & Yamaguchi, 1985; McGue & Iacono, 2005; Odgers et al., 2008; Sung et al., 2004);
2. **Quantity.** In general, the more drugs a person uses at the outset, the more likely he or she is to continue along the road to substance dependence (Bailey, 1992; D’Amico et al., 2001).

Note that the common liabilities model and the gateway hypothesis may both be correct, at least in some cases. And, in fact, they may be conceptually related: An underlying liability may lead some individuals to start experimenting with drugs earlier, or more intensely, than others. This earlier or more intense use of drugs may then lead some people with the underlying common liability to shift from entry drugs to harder drugs.

Substance Abuse as a Category or on a Continuum?

According to DSM-IV-TR, substance abuse and substance dependence are separate categories, and a habitual drug user is diagnosed with either substance abuse or substance dependence (or, in theory, does not meet the criteria for either diagnosis). However, some research suggests that the abuse/dependence distinction is artificial and that a more meaningful way to conceptualize harmful substance use, at least of alcohol, is on a continuum of severity (Heath et al., 2003; Langenbucher et al., 2004; Sher, Grekin, & Williams, 2005). According to this view, substance use, abuse, and dependence vary not qualitatively but rather quantitatively, with dependence on the extreme end of a continuum. This continuum is defined by the frequency, quantity, and duration of use (see Figure 9.3). The more frequent the use, the larger the quantity, and the longer the use has been going on, the more likely the use is to become abuse. And increasing frequency, quantity, or duration of use can push the diagnosis beyond abuse to dependence.

According to the continuum approach, we would determine whether any of the Beatles abused or was dependent on Preludin, for instance, based on how much, how often, and for how long each of them took the stimulant. This approach quantifies severity in a way that the DSM-IV-TR criteria do not (O’Malley, Johnston, & Bachman, 1999; H. A. Skinner, 1995).

Comorbidity

As we’ve noted in earlier chapters, many people with psychological disorders abuse substances, particularly alcohol, marijuana, cocaine, and opiates (Lingford-Hughes & Nutt, 2000). In a study specifically examining the prevalence of comorbid disorders among people with substance use disorders, almost half of those with alcohol abuse or dependence also had another DSM-IV-TR disorder—and almost three-quarters of those with drug abuse or dependence had another DSM-IV-TR disorder (Regier et al., 1993). Common comorbid disorders include mood disorders

Figure 9.3

9.3 ▶ A Continuum of Substance Use, Abuse, and Dependence

Substance use, abuse, and dependence may be better conceptualized as occurring on a continuum rather than as discrete categories. Where an individual’s use falls on the continuum would be determined by frequency, quantity, and duration.

IMPictures/FilmMagic/Getty Images

Using or abusing more than one substance can increase the risk of accidental overdose; actor Heath Ledger died in 2008 from taking a combination of drugs, reportedly for his chronic insomnia. The autopsy results indicated that he'd taken pain killers, several benzodiazepines (used to decrease anxiety), and an over-the-counter antihistamine that can induce drowsiness. He may have developed tolerance to standard doses of these medications; in combination, they caused his heart or breathing to slow down so much that he died (Falco, 2008).

Polysubstance abuse

A behavior pattern of abusing more than one substance.

(most frequently depression), posttraumatic stress disorder (PTSD), schizophrenia, and *attention-deficit/hyperactivity disorder* (ADHD, discussed in Chapter 14), a disorder marked by problems sustaining attention or by physical hyperactivity (Brady & Sinha, 2005).

When substance abuse develops after another psychological disorder has developed, clinicians may infer that the person is using substances in an attempt to alleviate symptoms of the other disorder—to self-medicate. John Lennon struggled with depression at different points in his life; even at the height of Beatlemania, he had a bout of depression (revealed in his lyrics for the song “Help!”). It is possible that his drinking and later heroin use were attempts to alleviate his depression.

Polysubstance Abuse

As was true of the Beatles, some people abuse more than one substance, a behavior pattern that is called **polysubstance abuse**. One study found that among alcoholics, 64% also suffered from drug abuse or dependence (Staines et al., 2001). Polysubstance abuse is dangerous because of the ways that drugs can interact: One lethal combination occurs when someone takes a drug that slows down breathing, such as barbiturates (which are often used as sleeping pills), along with alcohol. A form of polysubstance abuse that is seldom recognized is the combination of alcohol and cigarettes (nicotine): Cigarettes are the biggest killer of all drugs, and this is particularly true among alcoholics. Most alcoholics are more likely to die from nicotine-related medical consequences, such as cardiovascular disease, than from alcohol-related ones (Hurt et al., 1996). Elaine W., the subject of Case 9.2, abused a variety of substances.

CASE 9.2 ► FROM THE INSIDE: Elaine W.'s Polysubstance Abuse

I remember my first experience with alcohol like it was yesterday. It was prom night, May 1969, and I was 16 years old. [My date had some wine he took from his house.] Although we had not discussed this prior to the prom, and without even giving it a second thought I turned the bottle up and drank when it was passed to me. I remember that warm, mellow glow that accompanied that first drink and the feeling of security in believing that I had found what I had been searching for all my life; feeling like I belonged and that all was well with my world. From then on, drinking on the weekends was a regular occurrence. I was always the one who drank just to get sloppy drunk and pass out. I recognized even then that once I drank the first one I couldn't stop. I didn't see that as a problem though; just thought it was the way it was supposed to be. One of my friends found out quite by accident that if she took a pain pill before drinking it made the high much better. Naturally when she shared that information with me I had to try it. They were her mother's pills and she was right—I loved it.

After graduation from high school, the love of my life went away to college. On one of his weekends home he brought some pot with him and I smoked for the first time. I thought it was pretty cool because I could get really high and not have a hangover the next day. I still continued to drink though. Because of the pot smoking, the good friends I had in high school wouldn't have much to do with me anymore, so I had found new friends that liked the same things I liked; acid, pot, cocaine, and lots of alcohol.

Source: Faces and Voices of Recovery, 2007b.

Elaine took a variety of different drugs on different occasions, and she also took alcohol and pain medication at the same time. Fortunately, Elaine's sisters were able to get her to seek treatment and her polysubstance abuse stopped.

Prevalence and Costs

Substance abuse and dependence are among the more common psychological disorders. In 2007, 9% of Americans aged 12 and older, or 22.3 million individuals, were estimated to have substance abuse or dependence (Substance Abuse and Mental Health Services Administration [SAMHSA], 2008). Generally, men are more likely than women to be diagnosed with a substance abuse or dependence disorder,

although women are more likely to be diagnosed with abuse of, or dependence on, legally obtained prescription medications (Simoni-Wastila, Ritter, & Strickler, 2004).

The prevalence of drug use, abuse, and dependence varies across ethnic and racial groups in the United States. For instance, Asian Americans have the lowest rates of alcohol abuse or dependence (4%), whereas Native Americans have the highest rate (13%). Although African Americans are more likely to abuse or be dependent on illegal substances, they are the least likely, after Asian Americans, to be diagnosed with alcohol abuse or dependence (SAMHSA, 2008). Note that these prevalence rates group people who have somewhat different ethnic backgrounds into the same broad category, but this is a simplification: Within each broad ethnic or racial category, there can be significant variation. For example, among Americans of Hispanic descent, the 1-month prevalence rate of heavy drinking (five or more drinks in a sitting) for Cuban Americans is 1.7%, whereas it is 7.4% for Mexican Americans (NIDA, 2003). Therefore, prevalence rates of racial and ethnic groups provide only a general overview, and do so only at a particular moment in time.

Substance abuse and dependence affects not only the user but also family members and friends, coworkers and colleagues. Substance abuse and dependence are associated with violence toward family members and neglect of children (Easton, Swan, & Sinha, 2000; Gruber & Taylor, 2006; Stuart et al., 2003). When the substance abuser is a parent, the abuse can create chaos and stress in the family. Parents who abuse substances may feel guilty and ashamed about their abuse, which ironically may lead them to increase their substance use to cope with these feelings (Gruber & Taylor, 2006). Children may find themselves shouldering adult tasks and responsibilities (Haber, 2000). Children of parents who abuse substances are at increased risk of developing emotional and behavioral problems (Grant, 2000; Kelley & Fals-Stewart, 2002).

A parent's substance abuse can affect children in other ways. The parent's behavior ends up inadvertently providing a model of coping that the child may come to imitate, as was the case for Barbara:

With over 15 years of continuous sobriety I am still amazed at how my life has changed. As a young girl the message I received was: drinking, it was FUN, made people laugh and joke, not a care in the world. Later I would see it destroy our family due to an alcoholic mother. I swore I would never be like her. But I followed in her path, step by step. From my first drink to my last I was a blackout drinker. Somehow I managed to keep a job (sometimes) but I lost friends, respect and self esteem along the way. I never wanted to admit I had a problem, though I knew it all along.

(Faces and Voices of Recovery, 2007c)

Substance abuse and dependence also have costs for society as a whole, both financially and in human capital. One estimate placed the total economic cost of alcohol and drug abuse in the United States at around \$250 *billion a year*. These costs reflect the money spent by users in procuring the drugs, the government's costs in apprehending, bringing to trial, and incarcerating illegal drug users or dealing with the effects of illegal drug use (e.g., stealing in order to be able to buy drugs or driving under the influence of alcohol or drugs), and the costs of treating people for substance abuse and dependence (NIDA, 2006a). There is also a high correlation of substance abuse and dependence with unemployment, as is evident in Figure 9.4.

Culture and Context

The line between use and abuse, as well as that between abuse and dependence, shifts over time and across cultures and ethnic groups. For example, cocaine was used legally as a remedy for many ills in the second half of the 19th century, but it has now been illegal for decades. And, during the Prohibition era (1920–1933) in the United States, alcohol use was illegal.

Figure 9.4

9.4 ► Abuse, Dependence, and Unemployment

According to one national survey, 3% of Americans were dependent on or abused an illegal substance. Nine percent of those surveyed had alcohol abuse or dependence. As shown in the graph, a disproportionate number of people with abuse and dependence problems were unemployed at the time of the survey. The survey did not determine, however, whether their unemployment was a cause or a result of the substance abuse or dependence (SAMHSA, 2008).

Cultures may promote substance use in some contexts and not others. These Brazilian women are followers of Santo Daime, a spiritual practice that involves drinking *hoasca*, a tea made of plant-based hallucinogens. *Hoasca* is legal in Brazil and the United States when it is used as part of a religious practice.

Various cultures use psychoactive substances for different purposes. Some Native American tribes, for example, use peyote or psilocybin mushrooms (which, when eaten, produce vivid hallucinations) as part of sacred rituals. Similarly, tribal people in the South Pacific use *kava* (a beverage produced from the roots of a plant) and other substances as part of their rituals, which do not lead to substance abuse and dependence. Within these cultures, the use of psychoactive substances is strongly regulated, and there are penalties for abuse, including death (Trimble, 1994).

In addition, different cultures use alcohol differently. Patterns of use (or prohibition) can be divided into four categories (Room & Makela, 2000):

- *abstinence* (for example, in Muslim societies),
- *constrained* ritual use of alcohol (for example, among religious Jews),
- drinking as a *common* activity (as in some Mediterranean cultures), and
- “*fiesta*” *drunkenness* during community celebrations (such as Mardi Gras).

However, not all cultures fit neatly into one of these four categories, and within a given culture, subcultures may exhibit different patterns.

In the remaining sections of this chapter we discuss specific substances that are abused. We first describe what they are and consider the ways in which they have their effects. Because treatments for various types of substance abuse are similar, we consider treatment for all types of substance abuse in the final section of the chapter.

Key Concepts and Facts About Substance Use, Abuse, and Dependence

- The hallmark of substance use disorders is abuse of or dependence on a psychoactive substance.
- The term *addiction* focuses on the compulsive behaviors related to regular drug taking, but is not used in DSM-IV-TR.
- *Substance abuse* refers to the pattern of use of a psychoactive substance that leads to harmful effects; *substance dependence* refers to the persistent and compulsive use of a psychoactive substance, despite the ensuing negative consequences.
- Tolerance and withdrawal are common symptoms of substance dependence.
- Researchers have developed two compatible explanations of why substance use may lead to abuse. The common liabilities model focuses on underlying factors that may contribute to a variety of problem behaviors, including substance abuse. The gateway hypothesis focuses on factors that lead individuals to progress from using entry drugs to using harder drugs.
- In DSM-IV-TR, substance abuse and dependence are characterized as discrete categories; some researchers suggest that they may be better conceptualized as being on a continuum.
- Substance use disorders frequently co-occur with mood disorders (particularly depression), PTSD, schizophrenia, and ADHD. Many people with substance use disorders engage in polysubstance abuse.
- Cultures can promote or regulate substance use through the use of rituals and penalties.

Making a Diagnosis

- Reread Case 9.1 about Butch Jamieson, and determine whether or not his symptoms meet the criteria for substance abuse or substance dependence. Specifically, list which criteria apply and which do not. If you would like more information to determine his diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Stimulants

In 1960, when the Beatles first started playing in Germany (before they became famous in England), they worked at a club in Hamburg called Indra, where they had to play for 8 hours nightly. As noted earlier, they got through their performances by taking a legal stimulant (Preludin). Band members later reported that they did not fully realize that they were ingesting a stimulant. A bouncer at the club simply handed pills to the boys and suggested that they take them. The pills had their effect: The musicians played for hours and then stayed up for hours afterward, going to other clubs (Spitz, 2005). And Preludin wasn't the only stimulant that they took. They drank coffee and tea, and all of them smoked cigarettes, as seen in the movie *A Hard Day's Night*. These stimulants are legal, but there are others that are illegal. We'll consider both types.

Stimulants are named for their effect on the central nervous system—they *stimulate* it, causing increased activity and arousal. Stimulants include nicotine and amphetamines (including Ritalin), which are restricted, as well as cocaine, crack, and MDMA (Ecstasy, or “e”), which are illegal. At low doses, a stimulant can make the user feel alert, less hungry, and more energetic, mentally and physically.

People may use stimulants repeatedly in an effort to feel more energetic. However, there is a significant cost to such repeated use: a high likelihood of dependence. Stimulants also can cause a rapid or irregular pulse and heart failure.

What Are Stimulants?

In this section we first consider the illegal drugs cocaine and crack, then consider drugs that have both legal and illegal uses—amphetamines, methamphetamines, Ritalin, and MDMA (“Ecstasy”)—and end with a common substance that many people may not even realize *is* a stimulant—nicotine.

Cocaine and Crack

Derived from the coca leaf, cocaine was a popular medicine for various ailments in 18th-century Europe and North America. Its use was declared illegal at the beginning of the 20th century, after it became clear that the drug—and the quest for it—were impairing people's ability to function; it was being abused and leading to dependence (Rebec, 2000). Cocaine that is obtained in the form of a powder is typically inhaled, or “snorted”; as *crack*, a crystalline form, it is smoked.

Cocaine acts as a local anesthetic. Thus, when snorted, it leaves the user's nose feeling numb; repeated snorting can lead to diminished sense of smell and difficulty swallowing (NIDA, 2007b). Although the first few experiences of cocaine use may provide a heightened sense of well-being that can last for up to an hour, this positive state becomes increasingly harder to attain as tolerance develops (NIDA, 2007b).

Higher doses of cocaine bring many negative effects: paranoia, to the point of delusions; hallucinations, such as feeling insects crawling on the body when there are none; compulsive, repetitive behaviors such as teeth grinding; and increased heart rate and blood pressure with the accompanying risk of heart attack and sudden death. The hallucinations occur because cocaine causes sensory neurons to fire spontaneously. Users also lose their appetite, so those who are abusers or dependent on the drug may develop malnutrition. Table 9.4 lists these and additional effects of cocaine abuse. It is common for people with cocaine dependence to have alcohol dependence as well (Brady et al., 1995; Carroll, Rounsaville, & Bryant, 1993; Regier et al., 1990); when these two substances are used at the same time, the risk of sudden death increases (NIDA, 2007b).

Table 9.4 ▶ Effects of Cocaine Abuse

Long-term effects of cocaine	Medical consequences of cocaine abuse
Addiction Irritability and mood disturbances Restlessness Paranoia Hallucinations	Cardiovascular effects • disturbances in heart rhythm • heart attacks Respiratory effects • chest pain • respiratory failure Neurological effects • strokes • seizures and headaches Gastrointestinal complications • abdominal pain • nausea

Source: NIDA, 2004, p. 5.

Smoked crack acts more quickly than snorted cocaine and has more intense effects. Like snorting cocaine, smoking crack leads to a sense of well-being, energy, and mental clarity. However, this “high” usually lasts only minutes (NIDA, 2007b). As with other stimulants, when the high from crack evaporates, it leaves in its wake a sense of depression and craving for more of the drug, as related by Mr. R. in Case 9.3. These aftereffects may lead the user to take more of the drug, and may lead to dependence. Moreover, whereas dependence on cocaine may take months or even years to develop, dependence on crack can develop extremely rapidly—within weeks (NIDA, 2004; Rebec, 2000).

CASE 9.3 ► FROM THE INSIDE: Crack Dependence

Mr. R, a 28-year-old man, describes his dependence on crack.

I first started using cocaine about 4 years ago. I don't remember the first time I smoked the crack cocaine. It puts you in another world. I can't explain this euphoric feeling that it gives you, but it's a feeling I had never experienced before. I just want to sit there and enjoy the feeling and not think about anything or do anything. I have to keep doing it constantly to keep up the high.

I actually started staying out all night. I was smoking about 5 times a week and lost my apartment, lost everything. Everything was falling apart with my relationship, and I was starting to miss work a lot. But I just couldn't control it. You know, it overtook me. That's all I thought about and all I wanted to do was to keep smoking. Everything else was secondary.

An intense craving for me is when my heart starts beating fast—actually, I get a little sweaty—and all I think about doing is just going to smoke. That's it. Nothing else—everything that's on my mind just kind of disappears. First you start thinking about it, then your body almost reproduces the feeling that you get from a high.

The treatment center was an inpatient, intensive treatment program. It was a 6-month program and I stuck it out for 5 months. Then I moved into a halfway house and got myself a job. And one night, I wanted to smoke. I just said, “I want to smoke again. I want that feeling again.” And I went out and picked up again.

From pretty much then on, I have been using regularly about once a week, once every 2 weeks. Today I have 9 days clean. During the past month, I've used only 2 or 3 times, so I'm curbing it down. I'm getting really sick and tired of it, honestly, of the consequences and of the using. And I don't think the high is what it used to be. It's kind of getting monotonous to me. It's getting old. I don't know what it's going to take [for me to stop]. I know I'm the only one who can do it. You know, everyone can tell me to do this and do that, but not until I make that decision that I'm going to get clean 100%.

(Hyman, 2001, p. 25–87)

As often happens when people become dependent on a drug, Mr. R.'s life became focused on obtaining and using crack, and his intense cravings made it difficult for him to stop using the drug.

Amphetamines

Amphetamines typically produce the same effects as does cocaine, although these effects last longer. Common amphetamines include *benzedrine* (racemic amphetamine sulfate), *dexedrine* (dextroamphetamine), and *adderall* (a combination of amphetamine salts). Amphetamines are usually available as pills, which typically are swallowed, although the contents of the pills may be snorted or diluted and injected. Amphetamines are legally used to treat some disorders, particularly ADHD and the sleep disorder *narcolepsy*, in which the sufferer spontaneously falls asleep for brief periods of time.

With repeated use of amphetamines, people may become hostile toward others or develop a sense of grandiosity, as well as exhibit disorganized thinking or behavior (Krystal et al., 2005). Because tolerance develops, repeat users may take high doses, which can cause *amphetamine psychosis*, a condition characterized by paranoid delusions and hallucinations (symptoms similar to those of paranoid

schizophrenia; see Chapter 12). Abuse of, or dependence on, amphetamines can bring irreversible effects—including problems with memory and physical coordination—that arise from enduring changes in neurons (Volkow et al., 2001a), as well as reversible effects of irritability and violent behavior (Leccese, 1991; Wright & Klee, 2001). Withdrawal symptoms may include depression, fatigue, anxiety, and irritability. Mary Beth, discussed in Case 9.4, began using amphetamines not to experience a sense of euphoria, but to help her stay awake so that she could study more.

CASE 9.4 ► FROM THE OUTSIDE: Amphetamine Dependence

Mary Beth was a 20-year-old college student when she began using amphetamines to stay awake during the final exam period in the spring of her sophomore year. Although her exams didn't turn out very well (in part, because the drugs interfered with her ability to concentrate and remember), she continued to use them on and off over the next few months. Because tolerance gradually reduced the effects of the drug, she began taking more and more of it. Increasingly, the feelings of euphoria that at first had been induced by the drug were replaced by restlessness, irritability, and anger. People learned to stay away from her when she was studying late at night, because they knew she could lash out at them for the slightest provocation. Worse, though, were the profound feelings of depression that Mary Beth had begun to experience when the drug wore off. At those times, the best she could do (if she had no more drug to take) was to go to bed and try to fall asleep. The depression she experienced when she "crashed" was worse than anything she'd ever experienced before.

(Wilson et al., 1996, p. 286)

Methamphetamine

Another stimulant that is abused and leads to dependence is *methamphetamine* ("meth" or "speed"), which is chemically similar to amphetamines but has a greater and longer-lasting effect on the central nervous system. It can be inhaled, swallowed, smoked, or injected. Methamphetamine use can lead to an intense "rush" of pleasure, and use rapidly becomes abuse and then dependence as the person's life becomes focused on obtaining and using the drug. Both use of methamphetamine and the behaviors that are required to obtain it can impair functioning (NIDA, 2008a); as with all injected drugs, sharing needles increases the user's risk of contracting or spreading disease (such as HIV/AIDS). One man, Bill H., describes his dependence on methamphetamines after his first injection of the drug:

It was amazing. It also ruined my life. For the next 10 years my life went to hell. It was torture. I lost my job, family, respect, dignity, even my soul. I began doing things I still can't believe I've done. Lied, cheated, and screwed friend after friend until I had no friends at all. . . . I began to get paranoid, carried a 20-gauge sawed off shotgun around with me. . . . I saw people in trees, behind sofas, where there couldn't possibly be anybody there. It was a nightmare. That was 25 years ago; today I am a proud member of AA [Alcoholics Anonymous].

(Adapted from KCI, 2007)

Methamphetamine, like cocaine and amphetamines, can cause irritability, heart problems, hallucinations and paranoia at high doses (Ksir, 2000; NIDA, 2007e). Methamphetamine abuse can adversely affect the functioning of the neurotransmitters dopamine and serotonin, which leads to motor problems and impaired memory and emotional regulation; the increased blood pressure that results from taking the drug can cause strokes (NIDA, 2007e; Thompson et al., 2004). Table 9.5 summarizes the effects of long-term methamphetamine abuse. Some—but not all—of the brain damage inflicted by methamphetamine abuse is reversible with long-term abstinence (Volkow, Chang, et al., 2001a; Wang et al., 2004).

Table 9.5 ► Long-Term Effects of Methamphetamine Abuse

- Dependence
- Psychosis, including:
 - paranoia
 - hallucinations
- Repetitive motor activity
- Changes in brain structure and function
- Memory loss
- Aggressive or violent behavior
- Mood disturbances
- Severe dental problems
- Weight loss

Ritalin

Another legally restricted stimulant that is abused is *Ritalin* (methylphenidate hydrochloride), which—like amphetamines—is frequently prescribed for ADHD. Its neurological effect is similar to, but slower than, that of cocaine. Those who abuse Ritalin take the stimulant in any of three ways:

- swallowing pills, which does not usually lead to dependence;
- inhaling or snorting crushed pills, which leads to a quicker “high” and causes increased heart rate, stroke, or lung problems; and
- injecting the drug in liquid form, which is reported to produce an effect similar to that of cocaine.

Both inhaling and injecting Ritalin can lead to dependence. People who do not have ADHD may occasionally swallow Ritalin pills for the stimulant effects—heightened alertness, increased attention, and decreased appetite. Although such casual use does not meet the criteria for abuse or dependence, it still carries the risk of adverse medical side effects related to heart problems and stroke.

MDMA (Ecstasy)

Another stimulant drug that can be abused is *methylenedioxymethamphetamine* (MDMA), commonly called Ecstasy or simply “e.” MDMA is usually taken in tablet form. It is chemically similar to both methamphetamine and the hallucinogen mescaline and has the effects of both types of drugs: the stimulant effect of increased energy and the hallucinogenic effect of distorted perceptions. With the first use, people report heightened feelings of empathy toward others and a greater sensitivity to touch. This experience is less pervasive with subsequent use. Other effects are a sense of well-being and warmth toward others, reduced anxiety, and distortions of time perception (NIDA, 2007e). Abuse can result in poor mood and difficulty regulating emotions, as well as anxiety and aggression, sleeping problems, and decreased appetite (NIDA, 2008b).

In addition, MDMA users can also develop impaired cognitive functioning, especially problems with memory, after the drug wears off. These cognitive deficits become more severe when the drug is abused (Verkes et al., 2001). One survey of MDMA users found that almost 60% reported withdrawal symptoms that included poor concentration, depression, decreased appetite, and fatigue; moreover, almost half of these users were dependent on the drug (NIDA, 2007e; Stone, Storr, & Anthony, 2006). Frequent users of MDMA may experience tolerance and withdrawal symptoms (Leung & Cottler, 2008). Lynn Smith recounts her experience of MDMA dependence:

Sometimes I stopped eating and sleeping. I worked only two days a week to support my habit. The rest of the time was spent getting high, almost always on Ecstasy. The utter bliss of my first Ecstasy experience was a distant memory. Of course, I never could recapture that first high, no matter how much Ecstasy I took.

In five months, I went from living somewhat responsibly while pursuing my dream to a person who didn’t care about a thing—and the higher I got, the deeper I sank into a dark, lonely place. When I did sleep, I had nightmares and the shakes. I had pasty skin, a throbbing head and the beginnings of feeling paranoid.

(Partnership for a Drug-Free America, 2007)

MDMA’s side effects are similar to those of other stimulants, including increased blood pressure and heart rate. Excessive sweating, another side effect, can cause acute dehydration and hyperthermia (abnormally high body temperature). The effects of MDMA may be difficult to predict in part because the tablets often contain other drugs, such as ketamine, cocaine, or other stimulants; thus, many users’ experiences with MDMA are a result of unintentional polysubstance use (Green, 2004). In addition, many people who take MDMA also use other substances—intentional polysubstance use.

Nicotine

Nicotine—the active ingredient in tobacco—is a stimulant that leads to abuse and dependence and tobacco use is associated with cancer. When inhaled via cigarettes, nicotine is absorbed into the lungs. Nicotine can also be absorbed through the mucus membranes in the mouth and throat when chewed (chewing tobacco) or when smoked but not inhaled (pipe or cigar tobacco). Nicotine causes increased alertness, but also dizziness, increased blood pressure, and irritability. Cigarette smoking delivers not only nicotine into the smoker's bloodstream, but also carbon monoxide and tar to the lungs; chronic smokers have a higher risk of developing lung cancer and other breathing-related problems than do people who do not smoke (NIDA, 2007a). According to the National Institute of Drug Abuse (NIDA, 2006c), tobacco abuse and dependence is the number-one preventable cause of death in the United States: Almost half a million Americans die each year as a result of cigarette smoking. The health effects of cigarette smoking are also costly: \$75 billion is spent annually in the United States on related health care costs (NIDA, 2006c).

Nicotine withdrawal symptoms often include insomnia, anxiety, irritability, and concentration problems (Baker, Brandon, & Chassin, 2004). People who have nicotine dependence may report that the drug makes them feel relaxed. However, this may not be a direct effect of nicotine: Rather, when enough hours have elapsed since the last “hit” of nicotine, the dependent person may begin to have withdrawal symptoms, which include becoming irritable—and having another cigarette or wad of chewing tobacco produces the experience of “relaxation” as the irritability and jitteriness of withdrawal fade (NIDA, 2006c).

Many smokers try to quit several times before they are successful. George Harrison quit for a while but then resumed smoking until he was diagnosed with a smoking-related cancer, at which point he quit for good. Nicotine dependence can be so powerful that some people who develop smoking-related cancer continue the habit even after the cancer is diagnosed.

Understanding Stimulants

Each type of psychoactive substance can change the way the neurons function in specific brain areas. Depending on the substance, as well as the dose and the frequency of use, these brain changes can lead use to evolve into abuse and dependence. In turn, abuse and dependence can alter the way neurons communicate with each other and the ways various brain areas function and interact. With some substances, these changes may be permanent. In the following sections we examine how neurological factors contribute to stimulant abuse and stimulant dependence (and substance abuse more generally), again considering brain systems and neural communication. Because very little is known about how genes might influence stimulant abuse, that factor will not be considered. We'll begin by discussing the role of dopamine, which plays an important role with virtually all stimulants but especially with cocaine and methamphetamine. But dopamine isn't the whole story, as we shall see; we'll also consider additional general mechanisms and examine the bases of abuse of two particular substances: MDMA and nicotine. However, keep in mind that the major brain systems involved in substance abuse are not independent—they constantly influence each other through feedback loops, and these loops are probably at least as important as each system's individual contributions.

Brain Systems and Neural Communication I: Dopamine and Abuse

Particular brain structures have a role in stimulant abuse largely because of the effects of specific neurotransmitters, and so we consider brain systems and neural communication together.

The Dopamine Reward System

Dopamine plays a key role in both the pleasurable experience of taking stimulants and the abuse of stimulants (Kalivas & Volkow, 2005), as well as in the abuse of many other psychoactive substances. To see how, we need to consider the neural circuits that

DAVID MAGNUS/Rex Features courtesy Everett Collection

Although all the Beatles smoked cigarettes during their teenage years, some of them continued to smoke. George Harrison (at right) smoked heavily for almost all of his adult life, up to the point where he was diagnosed with throat cancer, in 1998. He also developed lung cancer, which led to his death in 2001.

Dopamine reward system

The system of neurons, primarily in the nucleus accumbens and ventral tegmental area, that relies on dopamine and gives rise to pleasant feelings.

rely on dopamine. To begin, let's consider one classic study. Researchers placed tiny electrodes in parts of rats' brains; when the rats pressed a lever, they got a small jolt of electricity, which activated neurons near the electrodes (Olds & Milner, 1954). The researchers discovered that the animals worked hard to receive electrical stimulation to certain parts of the brain. In fact, they sometimes seemed to prefer such stimulation to food or drink! (Which cannot help but remind us of some forms of drug abuse, in which users sacrifice food and drink for the drug.) This sort of finding eventually led researchers to define a "reward system" in the brain. This reward system includes the ventral tegmental area, which in turn activates the nucleus accumbens (see Figure 9.5). The neurons in this system rely on the neurotransmitter dopamine. In fact, if animals are given a drug that blocks the effects of dopamine, they will not work as hard to receive electrical stimulation in these areas (Fibiger & Phillips, 1988). For this reason, the reward system is usually referred to as the **dopamine reward system**.

A wide range of pleasurable activities, such as eating and having sex, activate the dopamine reward system. All stimulant drugs affect the dopamine reward system *directly* (Tomkins & Sellers, 2001). As we shall see when talking about other types of substances, some other types of substances (such as alcohol) also activate the dopamine reward system directly, and still other types of substances activate it indirectly

Figure 9.5

9.5 ▶ The Dopamine Reward System (a) Key brain areas and neural systems of the dopamine reward system. (b) Ways that the dopamine reward system is activated and altered by substance use, abuse, and dependence.

Note: Only the axon and synapse of the interneuron are shown, and for illustration purposes, there is only one terminal button of the dopamine neurons shown. In fact, the axon from the dopamine neuron has many terminal buttons.

by altering other brain areas or neurotransmitters that, in turn, affect dopamine (Leone, Pocock, & Wise, 1991).

Regular stimulant use (or other substance use) usually affects the dopamine reward system. Researchers have thus proposed the *dopaminergic hypothesis* of substance abuse: The rewarding effects of a drug arise directly or indirectly from the dopamine reward system (Koob & Le Moal, 2008; Robbins & Everitt, 1999a, 1999b; Tomkins & Sellers, 2001; Torrens & Martín-Santos, 2000). Because of the neural changes that occur with continued abuse, after a while, the person needs the substance to feel “normal” and experiences cravings when not using the drug.

As researchers have come to understand the dopamine reward system in more detail, they have begun to gain insight into an age-old puzzle: Why are some people more susceptible to becoming abusers than others? Do they have less “character” or a weak “moral compass”? No. In fact, at least part of the answer is that the dopamine reward system is more sensitive and responsive in some people. For example, in one study, participants were given an injection of the stimulant Ritalin. The researchers found that participants who rated the experience as pleasant had fewer dopamine receptors than those who found it unpleasant (Volkow et al., 1999). Such findings support the hypothesis that people with fewer dopamine receptors may be more vulnerable to drug use (and abuse); the smaller quantity of receptors means they have reduced activation in the reward system, which is boosted by substance use (Swanson & Volkow, 2002). In fact, rats bred so that they consume relatively high amounts of alcohol appear to have a less responsive dopamine reward system, which could explain why they drink more (McBride et al., 1990).

In addition, as we’ll discuss shortly, stimuli related to taking a drug—such as the music, lighting, and crowds at a dance club where cocaine use occurs—can become associated with drug use. Connections among different brain areas, such as the amygdala and hippocampus, store associations between drug use and the stimuli related to drug use. Once such associations are established, these drug-related stimuli themselves can trigger the dopamine reward system (Tomkins & Sellers, 2001). Moreover, simply perceiving such aspects of the environment can activate structures in the limbic system (Dackis & O’Brien, 2001), which is tightly tied to the dopamine reward system. For example, one such structure is the anterior cingulate, and an fMRI study found that this structure was activated when cocaine addicts simply watched videotapes of cocaine-related objects and events (Wexler et al., 2001).

Effects of Cocaine and Methamphetamine on the Brain

To see how the dopamine reward system is involved in drug abuse, let’s look at two abused drugs, cocaine and then methamphetamine. The effects of cocaine on the brain result from the way it affects dopamine levels. Specifically, cocaine binds to dopamine transporters—the molecules that take excess dopamine from the synapse and bring it back to dopamine-containing sacs within the terminal buttons of the transmitting neuron (see Figure 9.6). When cocaine binds to these transporter molecules, they don’t operate as effectively to remove dopamine from the synapses—and thus more dopamine

Figure 9.6

9.6 ► Cocaine Abuse and Dependence and Dopamine This schematic illustrates how cocaine binds to dopamine transporters, which prevents normal reuptake of dopamine back into the transmitting neuron and increases the amount of dopamine in the synapse, which thereby activates the dopamine reward system.

Figure 9.7

- (a) No history of methamphetamine use (b) 1 month after abuse stops (c) 1 year after abuse stops

9.7 ▶ Methamphetamine Abuse: Reversible and Irreversible

Brain Damage (a) This scan shows the distribution of dopamine transporters in a normal brain. (b) This scan shows the brain of a person who had used methamphetamine over a period of years; as is evident, even 1 month after this person stopped using the drug, the dopamine transporters are still in short supply. (c) This scan shows the brain of the same abuser more than a year after stopping the use of methamphetamine; although there is some recovery of function, the effects of chronic abuse are not completely reversed.

Source: Nora D. Volkow et al., *The Journal of Neuroscience*, December 1, 2001, 21 (23):9414–9418.

lingers there, which causes the receiving neuron to fire even when relatively little dopamine has been released by the sending neuron (Koob & Bloom, 1988; Koob, Sanna, & Bloom, 1998). Thus, relatively little stimulation can produce pleasurable sensations.

A similar mechanism is at work when someone takes methamphetamine. Again, the drug binds to the molecules that transport excess dopamine back to the terminal buttons and prevents them from operating effectively—thereby leaving more dopamine in the synapse, which in turn activates the dopamine reward system. Long-term use of methamphetamine disrupts the functioning of these transporter molecules. Moreover, as shown in Figure 9.7, not all of the damage inflicted on the brain by long-term methamphetamine abuse is reversible. The images in the figure show the distribution of dopamine transporters in the brain of a person who abused methamphetamine. As is evident, even 2 years after the person stopped using methamphetamine, the neurological effects of chronic abuse are not totally reversed.

Brain Systems and Neural Communication II: Beyond Dopamine

In this book we have emphasized that brain areas work together in systems, and often more than one system is involved in producing a particular behavior. This is true of stimulant abuse in particular, and substance abuse in general. Although the dopamine reward system plays a crucial role in leading people to abuse drugs, it is not the whole story. Many other neurotransmitters and their related brain systems have been implicated in drug abuse, but three are particularly important: gamma-aminobutyric acid (GABA), glutamate, and serotonin.

The GABAergic system—the term used for the system of neurons that rely on the neurotransmitter GABA—appears to play a particular role in the shift from recreational use to abuse and dependence (Brady, 2005; Kalivas & Volkow, 2005). The GABAergic system includes part of the frontal lobe—in particular, the prefrontal cortex—that is involved in motivated behavior (that is, behavior oriented toward a goal) and thus in drug-seeking behavior (Kalivas & Volkow, 2005).

The glutamate system—which consists of neurons that rely on the neurotransmitter glutamate—also plays a role in the shift from drug use to abuse and dependence. Glutamate receptors abound throughout the cortical and limbic regions that play a role in drug abuse, and researchers have shown that such receptors help to produce the reinforcing effects of drugs—which lead some people to become abusers—and also the negative effects experienced during withdrawal (Kenny & Markou, 2004). In fact, drugs that block glutamate receptors have been used to treat cocaine dependence and nicotine dependence (Ait-Daoud et al., 2006).

Finally, the serotonin system—which consists of neurons that rely on the neurotransmitter serotonin—plays a role in the abuse of stimulants. This is not surprising, given that this system is critical for the regulation of many basic biological functions, such as eating, drinking water, sexual behavior, and response to pain (Pihl & Peterson, 1995). Serotonin has been shown, for example, to play a role in producing the desire for cocaine (Aronson et al., 1995).

However, it's important to remember that the different neurotransmitters and brain systems work together and that their effects emerge from their interactions. As we have described, stimulants lead to increased dopamine production in the nucleus accumbens (and other dopamine-producing areas), and the higher level of dopamine not only has direct effects on the reward value of drugs but also indirectly modulates the activity of the GABAergic, glutamate, and serotonin systems. These systems can cause the drug to have rewarding effects and make other rewards (such as a good meal, an interesting conversation, or a paycheck) feel less valuable (Kalivas & Volkow, 2005).

Thus, although stimulants in general engage the dopamine reward system, this effect is not the only reason why some people come to abuse such drugs. Some stimulants also have more specific effects on the brain. For example, MDMA not only causes dopamine to be released, but also binds to serotonin transporters and

thereby creates excess serotonin in the synapse (analogous to the effect of cocaine on dopamine in a synapse; see Figure 9.6). This excess serotonin can have a calming, relaxing effect. However, high levels of serotonin in the synapse not only affect the receiving neuron, but also cause the sending neuron to produce less serotonin in the future. This effect persists even after the person has stopped using the drug. Moreover, in animals, even short-term use of MDMA can produce enduring damage to the terminal buttons of serotonin-releasing neurons, which in turn contributes to disrupted learning, memory, sleep, and appetite (NIDA, 2007e; Parrott, 2002). As a stimulant, then, MDMA not only affects the dopamine reward system, but also the serotonin system.

Finally, some stimulants operate on very specific receptors. For example, nicotine acts on a specific type of acetylcholine receptor called the *nicotinic receptor*. Such receptors are located on the cell bodies of dopamine-releasing neurons. Activation of these receptors leads to increased release of dopamine in the nucleus accumbens, as well as removing the inhibiting effect of other neurotransmitters (Picciotto, 1998; Tomkins & Sellers, 2001). The dopamine reward system is activated within 10 seconds of inhaling tobacco, which activates nicotinic receptors. Nicotine may activate brain areas in a pattern that parallels the brain areas affected by cocaine (Pich et al., 1997). Table 9.6 lists the neurological factors that contribute to the abuse of and dependence on stimulants.

Table 9.6 ▶ Neurological Factors That Contribute to the Abuse of and Dependence on Stimulants

- Stimulants bind to dopamine transporters, leading to increased dopamine in the synapse.
- Substance activates the dopamine reward system, specifically the nucleus accumbens and ventral tegmental area.*
- Associations between drug-related stimuli and drug use can activate the limbic system (and the dopamine reward system).*
- GABA, glutamate, and serotonin are involved in the shift from recreational drug use to abuse and dependence.*

*This factor is not unique to *stimulant* abuse and dependence.

Psychological Factors: From Learning to Coping

Various psychological factors contribute to stimulant abuse and dependence, and to substance abuse and dependence in general. One type of psychological factor is observational learning: Through observing others, people develop expectations about when to use drugs and what the experience of using a given substance should be like. These expectations in turn act as feedback that affects how the brain actually responds to a drug (Nitschke et al., 2006; Wager et al., 2004). Another psychological factor is operant conditioning: When the consequences (effects) of drug use are rewarding, the person is likely to use drugs again and again. Repeated drug use, in turn, can produce classical conditioning, whereby stimuli associated with drug use, such as the vial containing crack, elicit a *craving* (a strong urge or desire) for the drug (Epstein et al., 2009). Such factors affect each other and can become feedback loops that create a spiral of substance abuse and dependence.

Let's examine these psychological factors in more detail, first considering observational learning and then moving on to operant and classical conditioning—which are involved in the progression from use to abuse and dependence and in the maintenance of abuse and dependence once they develop.

Observational Learning

People may develop substance abuse or dependence, in part, through observing use or abuse of drugs by models—family members, peers, celebrities, or mentors. Not everyone who observes substance use or abuse will follow suit, but simply observing how other people use substances as a coping strategy can provide a model for that particular way to cope (Winfree & Bernat, 1998). For example, suppose a girl witnesses her respected older brother having an argument with their father. The brother and sister leave the house after the fight, and the brother proceeds to smoke crack while complaining about the father. Through observation, the younger sister learns that one way to cope with stress is through substance use. Similarly, studies have found that if a person's peers use or abuse substances, that person is likely to do the same (Dishion & Medici Skaggs, 2000; Fergusson, Swain-Campbell, & Horwood, 2002).

However, the relation between observing another person and then subsequently imitating his or her behavior is only a correlation—and, as we saw in Chapter 2,

correlation does not imply causation. It is possible that those who are at risk for developing substance abuse (perhaps because of a family history) may be more likely to seek out peers who are substance users. For instance, consider that people who have a high need for social approval are more likely to model their peers' behavior. So, it is possible that if peers abuse drugs, those desperate for social approval are more likely to use or abuse drugs than are people who resist peer pressure and do not respond strongly to peer approval (Caudill & Kong, 2001).

In any event, observational learning is an established fact. And it is possible that by watching others—such as parents or peers, for instance—children and young adults learn to expect drugs to produce certain kinds of experiences, even if they do not use substances as a coping strategy (Brown et al., 1999; Colder et al., 1997; Zamboanga et al., 2005). For instance, when the Beatles began smoking cigarettes during their early teens, they did so in part because such behavior was modeled by their parents and their community; in addition, they probably developed the expectation that smoking would be fun and might make them appear more attractive to girls. These positive expectancies, developed through observational learning, may have led them to continue to smoke, even if smoking was initially unpleasant.

Operant Conditioning

Operant conditioning exerts its influence on stimulant use and abuse (and substance use, abuse, and dependence more generally) in several ways. First, if stimulant use is followed by pleasant consequences, those consequences act as positive reinforcement (which leads to recurrent use). Research on the dopamine reward system shows that aspects of this type of learning have neurological underpinnings. In fact, the dopamine reward system begins to be activated with the *expectation* of a drug's positive effects (that is, the expectation of reinforcement), which leads to **reward craving**—the desire for the gratifying effects of using a substance (Verheul, van den Brink, & Geerlings, 1999). Reward craving occurs even if recent experiences of drug use have not been positive.

Second, stimulant use and abuse can independently lead to negative reinforcement—alleviating a negative state, thereby producing a desirable experience (remember that negative reinforcement is not the same as punishment). In fact, such negatively reinforcing effects contribute to substance abuse among people trying to manage the psychological aftereffects of physical or emotional abuse (Bean, 1992; Catanzaro & Laurent, 2004; Ireland & Widom, 1994; Stewart, 1996); in particular, using drugs may (temporarily) distract them from painful memories or their present circumstances, and hence be reinforcing.

Drug use may provide transient relief from negative states, but persistently using substances as the means of gaining such relief (as the coping strategy)—which may have been learned, in part, through observing how other people cope—doesn't generally work, despite the fact that while the drug is in the system it may seem to the person that it helps. Substance use may temporarily make a person less aware of or make him or her care less about life's difficulties, but it doesn't make those difficulties go away. When the substance wears off, the person is in the same situation, if not worse off because of the consequences of the substance use (e.g., "crashing" after the high wears off or missing a deadline because of being high). These continuing life challenges in turn require more coping, and the person can enter a downward spiral. If substance use becomes the dominant coping strategy, it inevitably becomes substance abuse and possibly dependence.

The temporary emotional relief provided by substance use can create cravings for the drug when an individual experiences negative emotions; this type of craving is sometimes referred to as **relief craving** (Verheul, van den Brink, & Geerlings, 1999). Both reward craving and relief craving can cause substance-dependent people to use drugs compulsively, even when they would like to quit. Thus, cravings are thought to play a primary role in maintaining substance dependence (Torrens & Martín-Santos, 2000).

A third way that operant conditioning contributes to substance abuse and dependence also involves negative reinforcement, but in this case because using the

Reward craving

The desire for the gratifying effects of using a substance.

Relief craving

The desire for the temporary emotional relief that can arise from using a substance.

substance can eliminate withdrawal symptoms. That is, once a substance develops dependence, he or she probably will experience withdrawal as the substance wears off—with symptoms that can range from mildly unpleasant to extremely unpleasant and potentially lethal. Substance use eliminates the unpleasant withdrawal state, which increases the likelihood of subsequent use. (Note that this type of desire to use a substance differs from relief craving, in which an individual has an urge to use a substance to reduce an uncomfortable state brought on by factors not related to withdrawal.)

Fourth, people who go on to abuse substances may respond more than others to a particular pattern of operant conditioning. Research has revealed that compared to people who don't abuse substances, people who do abuse substances are more likely to prefer smaller amounts of reinforcement that occur immediately after a behavior to larger amounts of delayed reinforcement (Bickel & Marsch, 2001). They also prefer larger but delayed losses (punishment) over smaller but more immediate losses (Higgins, Heil, & Lussier, 2004). Thus, when a substance abuser can choose between taking a drug (with immediate reinforcement, along with possible delayed losses or punishment) and not taking it (with a loss of immediate reinforcement), he or she may choose the immediate reward of drug use.

Classical Conditioning

Stimuli associated with drug use (such as drug paraphernalia) are referred to as **drug cues**, and they come to elicit conditioned responses through their repeated pairings with drug use. The drug cues are then associated with the reinforcing (positive or negative) effects of the drug and, in fact, drug cues can themselves elicit the activation of the dopamine reward system (Tomkins & Sellers, 2001). Being exposed to such cues—or even thinking about them—can lead to drug cravings (Hyman, 2005; Stewart, de Wit, & Eikelbloom, 1984). For example, people often handle money when buying cocaine and then use the cocaine shortly afterward; handling money can then become a conditioned stimulus. Thus, a person addicted to cocaine can come to crave it after handling money (Hamilton et al., 1998). Similarly, for cigarette smokers, certain conditioned stimuli—such as a full sensation in the belly after dinner—can lead to a craving for a cigarette among after-dinner smokers (Lazev, Herzog, & Brandon, 1999). Even after successful treatment for substance abuse, being exposed to drug cues can lead a former abuser to experience powerful cravings and can increase the risk of relapse (Hyman, 2005; Torrens & Martín-Santos, 2000).

Cravings do not last indefinitely, however. When a person craves a substance but does not use it, the craving normally disappears within an hour (Wertz & Sayette, 2001). Researchers have found that a person is more likely to feel the craving when he or she expects to be able to take the drug. Because expectations moderate cravings and cravings can lead to relapse, expectations play a role in causing relapses.

Table 9.7 summarizes the psychological factors that contribute to abuse of and dependence on stimulants.

Table 9.7 ▶ Psychological Factors That Contribute to Abuse of and Dependence on Stimulants

- Observational learning: People observe models using substances as a coping strategy and develop expectations about drug use.*
- Operant conditioning:
 - Positive reinforcement leads to subsequent expectations of reward, which in turn lead to reward craving.*
 - Substance use alleviates a negative state, which provides negative reinforcement and leads to relief craving; substance use can become a chronic coping strategy.*
- Classical conditioning: Drug cues elicit a craving*

*This factor is not unique to *stimulant* abuse and dependence.

Jonathan Torgovnik/Getty Images

A stimulus associated with substance use can lead a person to crave the substance. For some, simply handling money can cause a strong craving for cocaine.

Drug cues

The stimuli associated with drug use that come to elicit conditioned responses through their repeated pairings with use of the drug.

Social Factors

In addition to the neurological and psychological factors that contribute to stimulant abuse and dependence, various social factors can promote substance use, abuse and dependence. Specific negative patterns of family interactions and peer relations are associated with a higher risk of a subsequent substance use disorder. In addition, perceived social norms play a role, and less directly, sociocultural factors create a backdrop that makes some people more vulnerable to stimulant abuse and dependence, as well as to substance use disorders in general. Let's examine these social factors in more detail.

Family Relations

Research grounded in the stage theory (introduced earlier in this chapter), found that teenagers whose drug use progressed from marijuana to other illegal substances did not have close relationships with their parents (Andrews et al., 1991). However, this finding is only a correlation; it could be that the factors that led to drug abuse also soured relationships between teenager and parents or that bad relationships contributed to drug abuse—or that some third factor, such as a particular temperament, contributed to both factors. In addition, many studies have found that adolescents who have dysfunctional family interactions (for example, have experienced child abuse, violence in the household, or parental substance abuse) are more likely to use and abuse substances (Hawkins, Catalano, & Miller, 1992; Hesselbrock, 1986; Kilpatrick et al., 2000).

Peers

Friends do things together; they often have common views or activities they enjoy. It's not surprising, then, that peers' substance use can influence an individual's substance use and abuse (Brewer et al., 1998). The influence of peers can also help explain findings that support the gateway hypothesis about increasing drug use. Once a (susceptible) individual repeatedly uses an illicit entry drug, such as marijuana, he or she is then more likely to spend time with peers who also use this drug and become socialized into a subculture favorable to drug use. The person who sells the marijuana is also likely to sell harder drugs, such as cocaine, providing an opportunity to experiment with harder drugs (Hall & Lynskey, 2005).

Norms and Perceived Norms

Societies specify norms of behavior, which include the degree to which psychoactive substances can be taken without being considered abuse. The Beatles changed social norms, at least for a while, among some portions of the population, through their public association with drugs: their arrests for possession of illegal drugs, Paul McCartney's admission that he used LSD, and song lyrics referring to drug use, such as "I get high with a little help from my friends" from *Sgt. Pepper*. Many fans perceived that drug use was "in," that they would not be "hip" unless they used drugs too.

This observation highlights an important fact about social norms: It's a person's *perception* of the norms that is the key, not the actual social norms. Perceptions of social norms about drug use clearly affect drug use; that is, when people think that "everyone" in their school, neighborhood, social class, or clique uses drugs, they are more likely to use drugs themselves. In contrast, people who think that only a minority of their classmates, neighbors, or friends use drugs will be less likely to use drugs. The extent of the group's actual drug use is less important than what the individual *perceives* it to be.

Moreover, perceived norms can be distorted. Specifically, people tend to notice the behavior of others who are using substances (e.g., "They were high as kites") more than they do the behavior of those who do not use substances or use them only moderately (Perkins, 1997). This distortion may lead to an incorrect perception about the social norm of substance use—that it is more common than it actually is. This mistaken perception in turn can lead individuals to calibrate their substance use to the inaccurate norm and use drugs more heavily than the true norm.

Sociocultural Factors

In addition to family and friends, other social forces can nudge individuals closer to or further away from stimulant abuse and dependence as well as substance abuse generally. People who are experiencing economic hardship and are unemployed are more likely to develop substance use disorders (Reid et al., 2001; SAMHSA, 2000). Consider that children who grow up in economically disadvantaged neighborhoods are more likely to be exposed to ads for legal psychoactive substances (alcohol and cigarettes) and to have easier access to these legal psychoactive substances as well as to illegal ones. Children who live in such neighborhoods may also observe more substance abuse among family members, peers, or adults; as noted earlier, such modeling can have an adverse effect. Moreover, these children are also more likely to experience or witness traumatic events and develop PTSD (see Chapter 7), which is associated with substance abuse (Johnson, 2008; Stewart, 1996).

Society at large also influences substance use by establishing legal consequences (Torrens & Martín-Santos, 2000). Society's influence is also seen in how access to drug treatment centers is regulated and in the national policies that direct resources toward effective prevention and treatment programs. Table 9.8 summarizes the social factors associated with abuse of and dependence on stimulants.

As noted by the asterisks in Tables 9.6, 9.7, and 9.8, most of the factors that contribute to stimulant abuse and dependence also contribute to abuse of and dependence on other substances; the one exception is the specific neurological effects of stimulant drugs. Because most of the factors contribute to substance abuse and dependence generally, we do not examine the feedback loops among the factors until after we review all types of substance abuse and dependence.

Table 9.8 ▶ Social Factors That Contribute to Abuse of and Dependence on Stimulants

- Dysfunctional family interactions are correlated with the presence of substance use disorders.*
- An individual's substance use is related to that of his or her peers.*
- Norms and perceived norms influence substance use.*
- Substance use disorders are correlated with economic hardship and unemployment, perhaps in part because of easier access to drugs or more exposure to drugs in the environment.*

*This factor is not unique to *stimulant* abuse and dependence.

Key Concepts and Facts About Stimulants

- Stimulants, which increase arousal and brain activity, are the category of psychoactive substances most likely to lead to dependence. Unlike many other types of drugs, they act directly—rather than indirectly—on the dopamine reward system by binding to dopamine transporters in the synapse.
- Stimulants include cocaine and crack, amphetamines, methamphetamine, Ritalin, MDMA, and nicotine. Crack use is associated with the most rapid progression to dependence. In high doses, most of these stimulants can cause paranoia and hallucinations. With continued use, stimulants lead to tolerance and withdrawal.
- Neurological factors that contribute to abuse of and dependence on stimulants include activation of the dopamine reward system, which involves the nucleus accumbens and the ventral tegmental area.
- Psychological factors related to substance use disorders include learning: operant reinforcement of the effects of the drug,

classical conditioning of stimuli related to drug use (which leads to cravings), and observational learning of expectancies about both the effects of drugs and use of them to cope with problems.

- Social factors related to substance use disorders include the specific nature of an individual's relationships with family members, socioeconomic factors, and cultural and perceived norms about appropriate and inappropriate use of substances.

Making a Diagnosis

- Reread Case 9.4 about Mary Beth, and determine whether or not her symptoms meet the criteria for substance dependence on amphetamines. Specifically, list which criteria apply and which do not. If you would like more information to determine whether she has such a dependence, what information—specifically—would you want, and in what ways would the information influence your decision?

Despite practice pouring the same quantity of liquid regardless of the shape of the glass, participants in one study poured more into shorter glasses than into taller ones (Wansink & Ittersum, 2005). Even professional bartenders are prone to estimate the quantities in differently shaped glasses incorrectly.

Daniel Templeton/Alamy

Depressants

Ringo Starr and John Lennon both had long periods of alcohol dependence. Starr reported that he “wasted” some years on alcohol, initially feeling that drinking gave him confidence but realizing later that it really didn’t (Graff, 1989). And Lennon was frequently drunk during his 18-month separation from his wife, Yoko Ono.

What Are Depressants?

Alcohol is a depressant. Other depressants are opiates, barbiturates, and benzodiazepines such as *diazepam* (Valium). In contrast to stimulants, *depressants* tend to slow a person down, decreasing behavioral activity and level of awareness. Regular use of depressants tends to lead to tolerance, and discontinuing their use or cutting back on the dosage or frequency can produce withdrawal symptoms. In this section, we will discuss the effects of use, abuse of, and dependence on three types of depressants: alcohol, barbiturates, and benzodiazepines.

Alcohol

Approximately 50% of people in the United States aged 12 and older report that they have had at least one alcoholic beverage within the previous month (SAMHSA, 2008). But using a substance isn’t the same as abusing it. Approximately 6% of Americans aged 12 or older (15 million people) are considered either to abuse or to be dependent on alcohol. Those who start to drink alcohol earlier in life are more likely to develop a disorder related to drinking (SAMHSA, 2008). But alcohol abuse and dependence aren’t equally prevalent among all racial and ethnic groups: Native Americans have the highest prevalence of alcohol abuse and dependence (NIDA, 2003), and Blacks are 40% less likely than Whites to develop alcohol abuse (Grant et al., 2008).

Blood Alcohol Concentration

The quantity of alcohol isn’t the only variable that determines intoxication. In fact, the crucial variable is blood alcohol concentration, which is affected by the number of drinks consumed, the period of time over which they were consumed, the time since the individual has last eaten, the individual’s body weight, and the individual’s gender. Different concentrations of alcohol in the blood are associated with different neurological and psychological states (see Figure 9.8). In the United States, Canada, and Mexico, 0.08% is the legal limit of blood alcohol concentration for driving.

It can be harder than you might think to regulate just how much alcohol you drink. For example, pouring drinks into short, wide glasses may lead people to imbibe a larger dose of alcohol than intended. A study found that college students, as well as professional bartenders, were likely to pour 20% more alcohol into a shorter, wider glass than into a taller, narrower one. Even with practice, participants poured more into the wider glasses than the narrower ones (Wansink & Ittersum, 2005).

The same amount of alcohol will have a slightly greater effect on a woman than a man of the same size and weight, because men and women metabolize the drug differently (Frezza et al., 1990). This sex difference arises in part because women have, on average, less total water content in their bodies than do men, which means that ingested alcohol is less diluted (Greenfield, 2002; Van Thiel et al., 1988).

Not only do the effects of a given amount of alcohol differ by gender, but there are also individual differences. Some people have a more intense response to alcohol than do others. This variability appears to be mediated in part by genes (Schuckit, 1999), but it is also related to the level of tolerance an individual has acquired.

Binge Drinking

Binge drinking, or *heavy episodic drinking*, occurs when a person drinks until his or her blood alcohol concentration reaches at least 0.08% in a 2-hour period (which

Figure 9.8

Blood alcohol concentration (percentage)	Changes in thoughts, feelings, and behavior	Impaired functions and activities (continuum)
0.01 – 0.05	Relaxation Sense of well being Loss of inhibition	Alertness Judgment
0.06 – 0.10	Pleasure Numbing of feelings Nausea Sleepiness Emotional arousal	Coordination (especially fine motor skills) Visual tracking
0.11 – 0.20	Mood swings Anger Sadness Mania	Reasoning and depth perception Social behavior (e.g., obnoxiousness)
0.21 – 0.30	Aggression Reduced sensations Depression Stupor	Speech (slurred) Balance Temperature regulation
0.31 – 0.40	Unconsciousness Death possible Coma	Bladder control Breathing
0.41 and greater	Death	Heart rate (slowed)

9.8 ► Blood Alcohol Concentration and Its Effects Different blood alcohol concentrations are on average associated with different effects. People may be motivated to drink alcohol because of the way it can affect thoughts, feelings, and behavior, but the same effects can impair functioning and, with repeated use, lead to alcohol abuse. As shown in the graph on the right, alcohol's effects—both desirable and undesirable—may be experienced within a few minutes and last a number of hours. The more someone has had to drink, the more impaired he or she will be for a longer period of time.

generally translates into four or more drinks for women, five or more for men; one drink is equivalent to 12 ounces of beer, 5 ounces of wine, or 1.5 ounces of 80-proof liquor) (National Institute on Alcohol Abuse and Alcoholism National Advisory Council, 2004). Binge drinking is likely to occur when a person sets out to get drunk (Schulenberg et al., 1996). Repetitive binge drinking can lead to alcohol abuse or dependence.

The prevalence of binge drinking differs across the United States, often because of the type of colleges predominant in a state. For instance, students at colleges in California are less likely to binge drink than are college students in other states. California students tend to be older and are more often married (Wechsler et al., 1997), which may lead them to drink more responsibly. Men binge drink at higher rates than do women, and women at coeducational schools binge drink at higher rates than women at women's colleges (Dowdall, Crawford, & Wechsler, 1998). Binge drinkers are at increased risk for dangerous alcohol-related behaviors, such as driving while impaired (Wechsler et al., 1998), having unprotected sex, and engaging in more sexual activity than they would have when sober (Wechsler et al., 2002).

Alcohol Dependence

Chronic drinking leads to tolerance and withdrawal, and hence alcohol dependence. According to the National Institute on Alcohol Abuse and Alcoholism (2005), alcohol dependence is marked by four symptoms:

- *craving*, which is a strong need, or urge, to drink;

- *loss of control*, which consists of not being able to stop drinking once drinking has begun;
- *physical dependence*, which brings withdrawal symptoms, such as nausea, sweating, shakiness, and anxiety after stopping drinking; and
- *tolerance*, which causes a person to need to drink greater amounts of alcohol to get “high.”

CASE 9.5 ► FROM THE INSIDE: Alcohol Dependence

Caroline Knapp describes her alcohol dependence in her memoir *Drinking: A Love Story* (1997):

By that point I don't even think the alcohol worked anymore. Certainly drinking was no longer fun. It had long ago ceased to be fun. A few glasses of wine with a friend after work could still feel reassuring and familiar, but drinking was so need driven by the end, so visceral and compulsive, that the pleasure was almost accidental. Pleasure just wasn't the point. At the end I didn't even feel like myself until I had a drink or two, and I remember that scared me a little: alcohol had become something I felt I needed in order to return to a sense of normalcy, in order to think straight. After one or two drinks I'd feel like I'd come back into my own skin—more clearheaded, more relaxed—but the feeling would last for only half an hour or so. Another few drinks and I'd be gone again, headed toward oblivion.

(p. 231)

In Case 9.5, above, Knapp describes the four elements of alcohol dependence: craving (“need driven”), loss of control (she would continue to drink until she was “headed toward oblivion”), physical dependence (“something I felt I needed in order to return to normalcy”), and tolerance (the alcohol didn't have as strong an effect as it had initially).

Alcohol abuse and dependence are also associated with memory problems, in particular, *blackouts*, periods of time during which the drinker cannot later remember what transpired while he or she was intoxicated. Knapp (1997) described her blackouts: “Sometimes I'd be so drunk at the end of the night I'd have to drive home with one eye shut, to avoid double vision. Sometimes I'd wake up at Sam's [a friend's] house, in his bed, wearing one of his T-shirts. I don't think we ever had sex but I can't say for sure” (p. 154).

Sedative-Hypnotic Drugs

Sedative-hypnotic drugs reduce pain and anxiety, relax muscles, lower blood pressure, slow breathing and heart rate, and induce sedation and sleep. In general, drugs in this class cause disinhibiting and depressant effects similar to those of alcohol (impaired physical coordination and mental judgment and increased aggressive or sexual behavior). Although these psychoactive substances can lower inhibitions and bring a sense of well-being, they also can cause memory problems, confusion, poor concentration, fatigue, and even respiratory arrest (NIDA, 2008e). When sedative-hypnotic drugs are mixed with another depressant, such as alcohol, the combined effect can be lethal: The person's breathing and heart rate can slow to dangerously low levels. Chronic use of these drugs can lead to tolerance. Two general types of drugs are in this class: *barbiturates* and *benzodiazepines*.

Barbiturates

Barbiturates, which include *amobarbital* (Amytal), *pentobarbital* (Nembutal), and *secobarbital* (Seconal), are usually prescribed to treat sleep problems. Although use of a barbiturate is legal with a prescription, this type of medication is commonly abused by both those with a prescription and those who obtain the drug illegally. As with other depressants, repeated barbiturate use leads to tolerance, so the person takes ever larger doses to get to sleep or reduce anxiety. Barbiturate abuse can also lead to withdrawal symptoms, including agitation and restlessness, hallucinations,

confusion, and, in some cases, seizures (NIDA, 2005c). People who have become dependent on a barbiturate and want to discontinue or decrease their intake of the drug should do so only after medical consultation to determine an appropriate schedule for tapering off without inducing dangerous withdrawal symptoms; otherwise, abrupt discontinuation of the drug can lead to convulsions and death.

Benzodiazepines

Benzodiazepines are usually prescribed to alleviate muscle pain, to aid sleep, or as a short-term treatment for anxiety (see Chapter 7); however, long-term use leads to tolerance and withdrawal. Examples of benzodiazepines include *lorazepam* (Ativan), *triazolam* (Halcion), *chlordiazepoxide* (Librium), *diazepam* (Valium), and *alprazolam* (Xanax). As with barbiturate dependence, a person with benzodiazepine dependence should gradually taper off of the drug, in consultation with a physician. For people who are dependent on these drugs, abruptly stopping use can lead to seizures and psychosis.

Understanding Depressants

In what follows, we will first discuss how brain systems and neural communication are affected by depressants in general and then turn to the effects of alcohol in particular. A considerable amount is known about the genetics of alcoholism, and we'll look closely at these findings before considering psychological and social factors.

Neurological Factors

In this section, we consider a set of closely related topics: the effects of depressants on the GABAergic system, the neural bases of alcohol abuse and dependence, and the genetics of alcoholism.

Brain Systems and Neural Communication

Benzodiazepines (such as Valium), barbiturates, and alcohol directly affect the GABAergic system, which is widespread in the brain and primarily activates inhibitory neurons. The resulting inhibition affects neurons in brain structures that are involved in anxiety, such as the amygdala. As we've noted before, the amygdala plays a key role in fear, and hence inhibiting it dulls the sense of fear and the related feeling of anxiety. Thus, it is not surprising that people who experience anxiety, for whatever reasons, find the use of depressants particularly reinforcing. In fact, those who suffer from phobias or panic disorders are at high risk to abuse alcohol and other depressants (Pihl, 1999). Depressants also indirectly affect the dopamine reward system.

Like other depressants, alcohol inhibits neurons, which has the net effect of dampening—or depressing—the nervous system so that it is less responsive. However, some of the brain systems that are most affected by alcohol normally inhibit other brain systems, which thereby become disinhibited—which is why people may seem “looser” after a couple of drinks, perhaps by talking more than usual or acting impulsively. Alcohol has a number of distinctive effects, which we consider in the remainder of this section: the nature of withdrawal, hangovers, and indirect effects on nutrition.

Chronic Alcohol Drinking and Withdrawal Although alcohol consumption induces the production of dopamine, which is rewarding, chronic use of alcohol stimulates the production of a type of neurotransmitter called *endogenous opioids*, sometimes referred to as “pleasure chemicals.” (There is a class of drugs referred to as *opioids* or *opiates*, which we'll discuss later in the chapter. The word *endogenous*—means *originates within the body*—is used to distinguish the neurotransmitter opioids from the drugs of the same name.) Endogenous opioids are responsible for “runner's high,” the feeling that occurs when someone has pushed herself or himself to a physical limit and experiences a sense of deep pleasure. In chronic drinkers, the activity of endogenous opioids occurs only in response to alcohol; when they stop drinking, their bodies no longer produce endogenous opioids. Thus, when a chronic drinker

isn't consuming alcohol, he or she may experience symptoms related to opioid withdrawal, which are unpleasant. This experience in turn may induce the person to consume more alcohol to produce more opioids (Gianoulakis, 2001). In other words, with chronic use, drinking more alcohol may become negatively reinforcing—it removes an unpleasant state.

Figure 9.9

9.9 ► Alcohol Abuse and Dependence: Effects on the Brain

One of the effects of long-term alcohol dependence—alcoholism—is enlarged ventricles (the cavities in the brain filled with cerebrospinal fluid) (Rosenbloom, Sullivan, & Pfefferbaum, 2003). (a) The ventricles in this MRI scan are normal size; (b) the enlarged ventricles in this MRI scan are those of a man with alcohol dependence. The enlargement of the ventricles reflects the reduced size of a number of brain areas. These neurological changes may explain some of the memory problems associated with alcohol dependence.

Source: Rosenbloom, M., Sullivan, E.V., and Pfefferbaum, A. Using magnetic resonance imaging and diffusion tensor imaging to assess brain damage in alcoholics. *Alcohol Research & Health* 27(2):146–152, 2003.

Biological By-products of Alcoholism People who frequently drink a lot of alcohol may become malnourished when the calories in alcohol substitute for calories from food (Mehta et al., 2006). Such malnourishment can include a deficiency in vitamin B1, which eventually causes several key parts of the brain to atrophy—including the mamillary bodies and the thalamus. Because these brain structures are important for storing new information in memory, drinking a lot of alcohol can indirectly lead to chronic memory problems (which produces a condition called *Korsakoff's syndrome*). Figure 9.9 shows a result of such brain atrophy: the increased size of the fluid-filled hollow areas, the ventricles, in the center of the brain.

Frequent high levels of alcohol use can also adversely affect the liver, which filters impurities from the blood; when a person drinks too much alcohol for too long a period of time, the liver develops scar tissue, which affects its ability to function. This condition is known as *cirrhosis* of the liver; it is potentially lethal and more likely to occur when malnutrition is present along with alcohol abuse or dependence (Lieber, 2003).

Why We Get Hangovers A hangover occurs the day after a person has been intoxicated by alcohol, and consists of a bad headache, nausea, and perhaps feeling dizzy and disoriented. These symptoms arise in part because alcohol is dehydrating: Alcohol is, essentially, a toxin, and the kidneys use water to remove toxins in the blood. Thus, the more alcohol a person drinks, the more water the kidneys use in the process of clearing out this toxin. But becoming dehydrated is only part of the reason we get hangovers. While the kidneys are working to remove the toxin, so is the liver. The liver relies on a two-step process to break down alcohol. First, the liver converts alcohol into a substance called acetaldehyde (a chemical that is related to formaldehyde), which is another toxin; second, it converts acetaldehyde to acetate, which is harmless. However, some people's livers cannot effectively carry out the second step, leaving their bodies subject to a toxin produced by their own livers!

If a person has become alcohol dependent, he or she may discover that one way to reduce the symptoms of a hangover is to drink more alcohol. For people with alcohol dependence, a hangover is more than simply being dehydrated or even having excess levels of acetaldehyde. It is also an indication that their bodies are going through alcohol withdrawal as the alcohol leaves the system (Cicero, 1978); drinking more alcohol can temporarily diminish the discomfort of the withdrawal symptoms. For a heavy drinker, withdrawal symptoms include headaches, weakness, tremors, anxiety, higher blood pressure, seizures, and increased heart and breathing rates. An extremely heavy drinker can also experience fever, agitation and irritability, as well as more severe symptoms such as confusion, convulsions, and visual hallucinations. All these alcohol withdrawal symptoms are collectively referred to as **delirium tremens**, or “the DTs.” Such withdrawal symptoms normally begin within 4 days after the person last drank alcohol (Romach & Sellers, 1991). Delirium tremens can be potentially lethal; thus, when people with alcohol dependence are ready to stop drinking, they should have a physician supervise the process.

Genetics of Alcoholism

The tendency to abuse drugs is affected by genes. One sign of this is the fact that substance abuse disorders tend to run in families. However, only the genetics of alcoholism has been studied in depth. So, we will restrict our discussion of the genetics of depressant abuse and dependence to this single (very important) substance.

Delirium tremens (DTs)

The symptoms of alcohol withdrawal marked by confusion, convulsions, visual hallucinations, and fever.

Family and Twin Studies For centuries, observers ranging from novelists to law enforcement officials have noted that members of some families are more likely to abuse alcohol than are members of other families. In fact, biological offspring of alcoholics are about twice as likely to become alcoholics as people without such a family history (Cloninger, Bohman, & Sigvardsson, 1981; Goodwin et al., 1974; Nurnberger et al., 2004; Russell, 1990).

Twin studies have also provided evidence for a genetic contribution to alcoholism (Cadoret, 1990; Carmelli, Heath, & Robinette, 1993). For example, one study investigated male twins who had registered with a Swedish Temperance Board because of problems with alcohol abuse. The results indicated that 54% of the variation in such abuse could be attributed to genetics and 14% to family environment (Kendler et al., 1997). Other studies suggest that the genetic influence may not be as high with females (McGue, Pickens, & Svikis, 1992).

Alcoholism and Adoption Studies Sometimes the offspring of alcoholics are adopted by parents who are not alcoholics, and researchers have studied some of these children after they've become adults. One striking finding is that even when they were raised by nonalcoholic parents, children whose biological parents were alcoholics are much more likely to abuse alcohol as adults than are those whose biological parents were not alcoholics. Another interesting finding from such adoption studies is evidence that there may be two distinct forms of alcoholism, which arise in part from different genes (Sigvardsson, Bohman, & Cloninger, 1996). Type 1 alcoholism is less severe and becomes evident later in life, and the effects of the genes associated with it can be moderated by environmental factors (such as whether the adoptive father had a skilled versus an unskilled job). Type 1 alcoholism occurs in both men and women. In contrast, Type 2 alcoholism apparently emerges early in life and occurs only in men, and the effects of the genes associated with it outweigh environmental factors. Some researchers have reported that Type 2 alcoholism arises in males who are (as were their fathers) impulsive and antisocial (Cloninger, 1987). If further data confirm that there are two distinct types of alcoholism, which are affected in different ways by genes, this would have implications for both diagnosis and treatment. For example, psychological treatment might be more effective for those with Type 1 alcoholism, whereas medications might be more important to prevent or treat Type 2 alcoholism.

Alcoholism and Chromosomal Markers Other evidence for the genetic bases of alcoholism comes from studies that link a genetic marker (i.e., a previously identified sequence of DNA at a particular location on a chromosome), particularly a portion of chromosome 11, to the disorder (Blum et al., 1990). But the genetic story is not all negative. Genes can make an individual more vulnerable to a disorder, but they can also have the opposite effect: They can protect against alcoholism by making drinking an aversive experience. For example, Asians often have a gene that give them forms of two liver enzymes that amplify the effects of alcohol (Higuchi et al., 1995), causing the person to have the negative consequences of drinking (including heart palpitations and nausea) after drinking even a little alcohol—bypassing the pleasant (and reinforcing) sensations that other people experience with a lower dose of alcohol. Researchers have shown that (probably because this gene leads alcohol to have larger effects) people with the gene drink less alcohol (Luczak et al., 2002) and are less likely to be binge drinkers (Luczak et al., 2001).

However, it is clear that more than one or two genes play a role in alcohol abuse and dependence; a number of genes, operating together, influence whether a person will develop problems with alcohol (Gordis, 1996; Sher, Grekin, & Wilkins, 2005).

Finally, just as we saw for stimulants, neurological factors that contribute to abuse of and dependence on depressants include activation of the dopamine reward system, neural-based associations between drug-related stimuli and drug use, and the role of GABA and glutamate in shifting recreational drug use to abuse and dependence. Table 9.9

Table 9.9 ▶ Neurological Factors That Contribute to the Abuse of and Dependence on Depressants

- Increased activity of the GABAergic system leads to increased inhibition of anxiety-related brain structures.
- Depressants indirectly activate the dopamine reward system.
- Depressants generally cause the nervous system to be less responsive.
- Some substances directly activate the dopamine reward system, including the nucleus accumbens and the ventral tegmental area.*
- Associations between drug-related stimuli and drug use can activate the limbic system (and the dopamine reward system).*
- GABA and glutamate are involved in the shift from recreational drug use to abuse and dependence.*

*This factor is not unique to *depressant* abuse and dependence.

Cultural forces can influence substance use. In the reality television show *The Osbournes*, tobacco and alcohol use were verbally discouraged, but such substances were often apparent to viewers: packs of cigarettes or wine bottles on the table, a martini shaker in the background. These different types of communication sent mixed messages to viewers (Blair et al., 2005).

MTV/Courtesy: Everett Collection

summarizes the neurological factors that contribute to the abuse of and dependence on depressants.

Psychological Factors

Many of the psychological factors that contribute to stimulant abuse and dependence also contribute to depressant abuse and dependence (see the starred items in Table 9.7); in particular:

- observational learning of depressant use, which promotes expectations about experiences from such use and promotes such use as a coping strategy;
- operant conditioning, in which
 - positive reinforcement leads to positive expectations of depressant use and to reward craving;
 - negative reinforcement can lead to relief craving and to depressant use becoming a chronic coping strategy; and
- classical conditioning, whereby drug cues elicit cravings.

Let's examine in a bit more detail the role of coping strategies and expectations in alcohol use.

Some people use alcohol as a way to cope with their problems. Consider Charles's experience:

Charles, a high-school teacher with a long-standing problem of alcohol dependence, identified boredom and anger as key high-risk relapse factors. His problem with anger involved a pattern of avoiding interpersonal conflicts and letting his anger build up. Over time, Charles would reach a point of total frustration and use his angry thoughts and feelings to justify drinking binges. [He had perceived his anger to be a] "bad feeling that could only be expressed through drinking" . . . he often became upset and angry because of certain beliefs he held about how others "should" treat him.

(Daley & Salloum, 1999, p. 258)

Like Charles, some people use alcohol to try to cope with particular emotions. In Charles's case, it was anger; for other people, the emotions might be sadness, anxiety, fear, shame, or any of a range of other emotions (Gaher et al., 2006).

Not all people use alcohol (or other drugs) to cope with life's ups and downs; particular factors lead some people to have a higher risk of using alcohol to cope. One such factor relates to the trait of anxiety sensitivity (see Chapter 7): People who are high in this trait find alcohol to be very calming, which explains why an anxiety disorder frequently precedes an alcohol use disorder in people who have both kinds of disorders (Sher et al., 1999; Stewart, Zvolensky, & Eifert, 2001).

Finally, even when they are not related to a coping strategy, expectations of what will happen as a result of drinking can also affect behavior after drinking (Kirsch & Lynn, 1999): People who drink to get "wasted" are in fact more likely to have that experience than are people who drink while having dinner with friends in a restaurant, even when people in both situations end up with the same blood alcohol concentration.

Social Factors

A variety of social factors can contribute to substance abuse and dependence (see the starred items in Table 9.8). For depressants, including alcohol, such factors include:

- dysfunctional family interactions (such as child abuse or neglect);
- peers' use of depressants;
- norms or perceived norms about depressant use (as in a subculture where drinking is the norm or is perceived to be so); and
- economic hardship and unemployment.

The relationship between alcohol use norms and perceived norms has been studied in depth. In the next sections we examine how alcohol abuse is affected by changing cultural norms about alcohol and differing community norms.

Changing Cultural Norms and Alcohol Abuse

Culture affects both the degree of alcohol abuse and the ways in which alcohol is used. For example, the rate of alcohol dependence among American women has increased over time. Historically, women in the United States had much lower rates of alcoholism than did men, but as social mores and roles for women changed, the incidence of alcoholism among women has come to approach that of men (Greenfield, 2002).

Moreover, cultures create social norms for appropriate and inappropriate use of alcohol, such as allowing “fiesta” drunkenness on certain occasions (Finch, 2001; Room & Makela, 2000). The media provide another source of influence. One correlational study found that adolescents and young adults who saw more ads for alcohol drank more alcohol (Snyder et al., 2006), possibly because seeing more ads for alcohol led them to perceive the norm for alcohol use to be greater than it was.

Community Norms, Diversity, and Drinking

Some of the social factors that affect alcohol abuse may seem surprising at first glance. For example, in one study, researchers examined rates of alcohol use in the highest-risk college-aged group (white men) and found that white men who attended colleges that have more diverse students—minority, women, and older students—were less likely to binge drink, even if they had been binge drinkers in high school (Wechsler & Kuo, 2003). Moreover, white men who did not binge drink in high school and went to colleges with more diverse students bodies were less likely to start binge drinking than were their counterparts who attended colleges with less diverse student bodies. One possible explanation for this finding is that a more diverse student body—with a wider range of views about binge drinking—prevented a social norm of high levels of binge drinking from developing. The only ethnic group more likely to binge drink and have an alcohol disorder than white Americans is Native Americans. In contrast, Asian Americans and black Americans aged 20 and under are the least likely to binge drink (SAMHSA, 2008).

Most of the factors that contribute to depressant and stimulant abuse and dependence—and the mechanisms related to those factors—also contribute to abuse of, and dependence on, other types of substances. For this reason, we explain the feedback loops among the factors only after we discuss all types of substance abuse and dependence.

Key Concepts and Facts About Depressants

- Depressants decrease arousal, awareness, and nervous system activity level. Depressants include alcohol, barbiturates, and benzodiazepines.
- Continued use of depressants leads to tolerance and withdrawal. Some withdrawal symptoms are potentially lethal; people with a dependence on depressants should be medically supervised as they taper off their use of the drug. Using more than one depressant at the same time is also potentially lethal.
- The effects of alcohol depend on its concentration in the blood. Repeated binge drinking can lead to alcohol abuse or dependence. Long-term alcohol dependence is associated with a variety of cognitive problems, as well as atrophy of certain brain areas and enlarged ventricles. Withdrawal symptoms include delirium tremens.
- Depressants directly affect the GABAergic system, which in turn dampens activity in key brain areas that give rise to anxiety; for this reason, people with anxiety symptoms are more likely than others to abuse depressants. Depressants also indirectly activate the dopamine reward system.
- Psychological factors related to depressant abuse and dependence include observational learning to expect specific effects from depressant use and to use depressants as a coping strategy, positive and negative reinforcement of the effects of the drug, and classical conditioning of drug cues that leads to cravings.
- Social factors related to abuse of and dependence on depressants include the nature of an individual's relationships with family members, peers' use of depressants, norms and perceived norms about appropriate and inappropriate use of depressants, and socioeconomic factors.

Making a Diagnosis

- Reread Case 9.5 about Caroline Knapp, and determine whether or not her symptoms meet the criteria for alcohol dependence. Specifically, list which criteria apply and which do not. If you would like more information to determine whether she has alcohol dependence, what information—specifically—would you want, and in what ways would the information influence your decision?

Other Abused Substances

This chapter has focused so far on stimulants and depressants because they are the most commonly abused substances. However, they are not the only substances that people abuse. In this section we briefly review three classes of other substances that are often abused: narcotic analgesics (such as codeine and heroin), hallucinogens (such as marijuana), and dissociative anesthetics (such as ketamine).

What Are Other Abused Substances?

By 1969, the Beatles had not performed for 3 years. In that year, they agreed to perform and have their rehearsals filmed. They spent a month in a recording studio composing and arranging songs, learning their parts, and rehearsing the songs. Rather than a true concert, however, the project culminated in a live, rooftop performance that was filmed. Some of this arduous process and the final concert were captured in the film *Let It Be*, which shows glimpses of the effects of John Lennon's heroin use. Lennon had difficulty remembering his lines from hour to hour and day to day, had trouble getting up each morning and arriving at the sessions on time, and had difficulty concentrating on writing and finishing songs (Spitz, 2005; Sulpy & Schweighardt, 1984). Such problems are typical of heroin use in particular and of the use of narcotic analgesics more generally.

Narcotic Analgesics

Narcotic analgesics are derived from the opium poppy plant or chemically related substances; narcotic analgesics are sometimes referred to as *opiates*, or *opioids*. To distinguish them from endogenous opioids, narcotic analgesics are sometimes referred to as *exogenous opioids* (*exogenous* means *arising from an outside source*). Exogenous opioids include methadone and heroin (to be discussed in more detail shortly), as well as codeine, morphine, and synthetic derivatives found in prescription pain relief medications such as *oxycodone* (OxyContin), *hydrocodone* (Vicodin), *meperidine hydrochloride* (Demerol), *propoxyphene* (Darvon), and *hydromorphone* (Dilaudid). These drugs can be injected, snorted, or taken by mouth. Legal but restricted narcotic analgesics are generally prescribed for persistent coughing, severe diarrhea, and severe pain. However, some people abuse these medications, taking them not for their medical effects but instead for the “high” they produce (NIDA, 2008a).

All analgesics relieve pain, and people who take analgesics for recreational purposes may temporarily experience pleasant, relaxing effects. However, this category of drugs is highly addictive—their use rapidly leads to tolerance and withdrawal and compulsive behavior related to procuring and taking the drug. Narcotics depress the central nervous system, and can cause drowsiness and slower breathing, which can lead to death if a narcotic analgesic is taken with a depressant. Although users may experience euphoria after taking a narcotic analgesic, that fades to apathy, unhappiness, impaired judgment, and psychomotor agitation (the “fidgets”) or psychomotor retardation (sluggishness). Users may also experience confusion—as happened to John Lennon—as well as slurred speech, sedation, or unconsciousness.

Withdrawal from a narcotic analgesic begins within 8 hours after the drug was last used. Withdrawal symptoms peak within several days, but can last for a week or more. Physical symptoms of withdrawal include nausea and vomiting, muscle aches, tearing from the eyes, dilated pupils, sweating, fever, diarrhea, and insomnia; many of the symptoms are similar to those of a bad case of the flu. Depressed mood, irritability, and a sense of restlessness are also common during withdrawal.

Heroin

Heroin is one of the stronger opioids and is very addictive. Unfortunately, the contrast between the euphoria that the drug induces and the letdown that comes when its effects wear off can drive some individuals to crave the euphoria, and so they

Photodisc/Alamy

Although some narcotic analgesics are derived from the opium poppy plant, others are synthetic derivatives. Repeated use of any type of narcotic analgesic rapidly leads to tolerance and withdrawal—signs of dependence.

take the drug, again and again—which in turn leads to tolerance. Tolerance makes the same dose of heroin fall short: Instead of causing euphoria, it often causes irritability. Extraordinarily unpleasant withdrawal symptoms can arise within a few hours of the last dose, peak within 72 hours, and take up to a week to subside; symptoms include bouts of chills and hot flashes, diarrhea, and extreme restlessness (NIDA, 2007c). Debbie describes her first experience with heroin:

[It's] as if you're drifting off into a deep, deep, deep, deep sleep. . . . You've got no feeling in a way. It feels like you're dead, you're [sic] body's dead in some ways but it's still warm. . . . You feel like you're in this little bubble and nobody can burst it but at the same time, you don't realise [sic] how much danger you're in.

(Substancemisuse.net, 2007)

Debbie goes to describe heroin withdrawal, after 2 years of daily use:

You're like a wild animal. You feel like you're climbing the ceiling. You're pulling your hair out. . . . You hit yourself, you know, to try and bring yourself out of it, to get that pain away. . . . you have stomach cramps, you feel sick. You don't know whether to put your arse on the toilet or your face down it. You can never get comfortable . . .

. . . my skin was getting turned inside out and there were things crawling underneath it. . . . It felt like my head was going to blow up. . . . I didn't know what to do. I was having hot and cold [flashes]. I didn't know whether to get dressed and go out looking but there was nothing anywhere. . . . You get very nasty and violent coz I did and I'm not a very violent person . . . that day I really did go for it and, you know, "Without that [heroin] I can't live," that's what got into my head "Without that [heroin] I can't live."

(Substancemisuse.net, 2007)

Debbie's experience with heroin withdrawal apparently involved many of the classic symptoms including chills and hot flashes, and restlessness.

Progression to Injection

Most people with substance abuse and dependence didn't begin by using a "hard" drug but progressed to such a drug over time; similarly, people who inject heroin ("shoot up") didn't necessarily start their heroin use that way. People rarely, if ever, *plan* to become addicted—rather, they just slip into this pathological state. Surveys of people who have used heroin find that the typical user starts out snorting heroin (as Lennon did), progresses to injecting heroin under the skin but not into blood vessels (termed *skin popping*), and then ends up injecting into blood vessels (termed *mainlining*). Injecting heroin causes a more intense experience: a "rush," a feeling of immediate intensity. Some users who inhale heroin do so because they mistakenly believe that this method of use is less likely to lead to tolerance and withdrawal (NIDA, 2005a). Most users proceed from occasional use to daily use, and their primary motivation in life becomes obtaining enough money to procure the next dose, or "fix." Because users become tolerant to the drug, they must increase the amount they use in order to get an effect. But their habit becomes a tightrope walk: Too great an amount is fatal.

Heroin abuse and dependence is associated with a variety of medical problems, such as pneumonia and liver disease. In addition, heroin often has various other substances added to it; these substances can clog blood vessels leading to vital organs. Moreover, abusers who inject the drug are at risk to develop AIDS and hepatitis as well as collapsed veins (NIDA 2007c).

Hallucinogens

In 1964, the Beatles began their search for the meaning of life through transcendental meditation, Hinduism, and "mind-altering" drugs such as lysergic acid diethylamide (LSD, also known as *acid*). George Harrison recounted that he had heard that hippies in the Haight-Ashbury district of San Francisco, California, were "dropping acid" in a similar search for meaning. Harrison flew there but was disgusted to find that the hippies generally weren't using LSD to seek enlightenment, but simply as another way to get high. Harrison was so disillusioned that he stopped using LSD in his search for meaning. Unlike other types of drugs we've discussed so far, hallucinogens

are less predictable in their effects, and are more sensitive to the user's expectations as well as the context in which the drug is taken.

Hallucinogens are substances that induce sensory or perceptual distortions—hallucinations in any of the senses. That is, they lead users to think they see, hear, taste, or feel something that is not actually present or not present in the way it is perceived. Some hallucinogens also can induce mood swings. Hallucinogens frequently taken for recreational purposes include the following:

- *LSD* (a synthetic hallucinogen),
- *mescaline* (a psychoactive substance produced by some kinds of cacti),
- *psilocybin* (a psychoactive substance present in psilocybin mushrooms, commonly referred to as “magic mushrooms”), and
- *marijuana* (the dried leaves and flowers of the hemp plant).

The first three of these drugs are chemically similar to the neurotransmitter serotonin. A single moderate dose of any of these drugs (or a very high dose of marijuana) is enough to induce visual hallucinations. Let's examine the abuse of and dependence on LSD and marijuana.

LSD

All of the Beatles used LSD at one point or another, but John Lennon reported that he took LSD thousands of times—which surely would constitute abusing the drug. LSD is a hallucinogen because it alters the user's visual or auditory sensations and perceptions; it also induces shifting emotions. Users may also experience *synesthesia*, a blending of senses that might lead them to “see” musical notes or “hear” colors. At higher doses, LSD can lead to delusions and distortions of time (NIDA, 2007d). LSD normally has an effect within 30 to 90 minutes of being ingested, and the effects last up to 12 hours (NIDA, 2001).

However, the effects of LSD can be unpredictable. A “bad trip” (i.e., an adverse reaction to LSD) can include intense anxiety, fear, and dread; a user may feel as if he or she is totally losing control, going crazy, or dying. People who are alone when experiencing a bad trip may get hurt or kill themselves as they respond to the hallucinations. If other people are present, they can talk the user through the effects, constantly reminding him or her that the trip is actually a temporary, drug-induced state; alternatively, they may take the person to the emergency room of a hospital.

Two aftereffects can occur from LSD use, even after the pharmacological effects of the drug have worn off: psychosis (hallucinations and visual disturbances) and “flashbacks” (termed *hallucinogen persisting perception disorder* in DSM-IV-TR, which are involuntary and vivid memories of sensory distortions that occurred while under the influence of the drug). However, such aftereffects are rare.

Recurrent LSD use can rapidly lead to tolerance, meaning that the user needs larger doses. Tolerance disappears if the user stops taking the drug, and LSD does not cause withdrawal symptoms. Unfortunately, LSD abuse can induce enduring psychotic symptoms in a small number of people (NIDA, 2007d).

Marijuana

The Beatles also smoked *marijuana*, which is the dried leaves and flowers of the hemp plant (*cannabis sativa*). The resin from the hemp plant's flowering tops is made into another, more potent drug, *hashish*. The active ingredient of marijuana and hashish is *tetrahydrocannabinol* (THC). Both marijuana and hashish can be either smoked or ingested. George Harrison used hashish and was arrested for possessing it. Paul McCartney and John Lennon were arrested at different times for possessing marijuana.

Marijuana's effects are subtler than those of other hallucinogens, creating minor perceptual distortions that lead a person to experience more vivid sensations and to feel that time has slowed down (NIDA, 2005b). The user's cognitive and motor abilities are also slowed or temporarily impaired, which produces poor driving

skills (Ramaekers et al., 2006). THC ultimately activates the dopamine reward system (NIDA, 2000).

Like the effects of LSD, marijuana's effects depend on the user's mood, expectations, and environment. For example, one study found that participants who were given THC and knew that they were receiving THC liked the effects and wanted more than did participants who were told they were receiving an antinausea drug but actually received THC (Kirk, Doty, & de Wit, 1998).

A user of marijuana who develops abuse or dependence will experience withdrawal symptoms after he or she stops using marijuana; such symptoms include irritability, anxiety, depression, decreased appetite, and disturbed sleep (Budney et al., 2004; Kouri & Pope, 2000). Studies have found that chronic marijuana use adversely affects learning, memory, and motivation—even when the user has not taken the drug recently and is not under its direct influence (Lane et al., 2005; Pope et al., 2001; Pope & Yurgelin-Todd, 1996). Smoking marijuana is also associated with an increased risk of heart attack (Mittleman et al., 2001). One survey found that of the approximately 7 million Americans who abuse or are dependent on an illegal substance, over half of them abuse or are dependent on marijuana (SAMHSA, 2004).

Dissociative Anesthetics

A *dissociative anesthetic* produces a sense of detachment from the user's surroundings—a *dissociation*. The word *anesthetic* in the name reflects the fact that many of these drugs were originally developed as anesthetics to be used during surgery. Dissociative anesthetics act like depressants and also affect glutamate activity (Kapur & Seeman, 2002). These drugs can distort visual and auditory perception. Drugs of this type have been referred to as “club drugs” because they tend to be taken before or during an evening of dancing at a nightclub. The most commonly abused members of this class of drugs are phencyclidine and ketamine, which we discuss in the following sections.

Phencyclidine (PCP)

Phencyclidine (PCP, also known as “angel dust” and “rocket fuel”) became a street drug in the 1960s. It can be snorted, ingested, or smoked, and users can quickly begin to take it compulsively. PCP abusers may report feeling powerful and invulnerable while the drug is in their system, and they may become violent or suicidal, at which point they may end up in an emergency room (NIDA, 2007f). Possible medical effects of high doses include a decrease in breathing and heart rates, dizziness, nausea and vomiting, seizures, coma, and death; coma and death are more likely if PCP is used along with one or more other drugs. With abuse can come memory, speech, and cognitive problems, even up to a year after the last use (NIDA, 2007f).

PCP has deleterious effects even when taken at low to moderate doses. Medical effects include increased blood pressure, heart rate, and sweating, coordination problems, and numbness in the hands and feet. At higher doses, PCP users may experience symptoms of hallucinations, delusions, paranoia, disordered thinking, and other symptoms of schizophrenia (see Chapter 12), which may bring them to the attention of mental health professionals, as occurred for the man in Case 9.6. Repeated PCP use can lead to craving for, and compulsive use of, the drug (NIDA, 2008d).

CASE 9.6 ► FROM THE OUTSIDE: PCP Abuse

The patient is a 20-year-old man who was brought to the hospital, trussed in ropes, by his four brothers. This is his seventh hospitalization in the last 2 years, each for similar behavior. One of his brothers reports that he “came home crazy,” threw a chair through a window, tore a gas heater off the wall, and ran into the street. The family called the police, who apprehended him shortly thereafter as he stood, naked, directing traffic at a busy intersection. He assaulted the arresting officers, escaped from them, and ran home screaming threats at his family. There his brothers were able to subdue him.

continued on next page

On admission, the patient was observed to be agitated, with his mood fluctuating between anger and fear. He had slurred speech and staggered when he walked. He remained extremely violent and disorganized for the first several days of his hospitalization, then began having longer and longer lucid intervals, still interspersed with sudden, unpredictable periods in which he displayed great suspiciousness, a fierce expression, slurred speech, and clenched fists.

After calming down, the patient denied ever having been violent or acting in an unusual way (“I’m a peaceable man”) and said he could not remember how he got to the hospital. He admitted using alcohol and marijuana socially, but denied phencyclidine (PCP) use except for once, experimentally, 3 years previously. Nevertheless, blood and urine tests were positive for phencyclidine, and his brother believes “he gets dusted every day.”

(American Psychiatric Association, 2002, pp. 121–122)

Ketamine

Ketamine (“Special K” or “vitamin K”) induces anesthesia and hallucinations and can be injected or snorted. Ketamine is chemically similar to PCP but is shorter acting and has less intense effects. With high doses, some users experience a sense of dissociation so severe that they feel as if they are dying (NIDA, 2001). Ketamine use and abuse are associated with temporary memory loss, impaired thinking, a loss of contact with reality, violent behavior, and breathing and heart problems that are potentially lethal (Krystal et al., 2005; White & Ryan, 1996). Regular users of ketamine may develop tolerance and cravings (Jansen & Darracot-Cankovic, 2001).

Understanding Other Abused Substances

We first consider brain systems and neural communication for each separate class of abused substances and then look at genetics. We’ll then examine psychological and social factors.

Neurological Factors

Depending on the abused substance, different brain systems and neural communication processes are critical, as we’ll see in the following sections.

Brain Systems and Neural Communication

Narcotic analgesics (heroin, in particular), hallucinogens, and dissociative anesthetics have different effects on brain systems and neural communication.

Narcotic Analgesics Among the narcotic analgesics, researchers have focused most of their attention on heroin—in large part, because it poses the greatest problem.

Like other opioids, heroin slows down activity in the central nervous system. It directly affects the part of the brain involved in breathing and coughing—the brainstem—and thus historically was used to suppress persistent coughs. In addition, heroin binds to opioid receptors in the brain, which has the effect of decreasing pain, and indirectly activates the dopamine reward system (NIDA, 2000). Continued heroin use also decreases the production of endorphins, a class of neurotransmitters that act as natural painkillers. Opioids such as heroin bind to the same receptors as endorphins do. Thus, heroin abuse reduces the body’s natural pain-relieving ability. Furthermore, someone with heroin dependence has his or her endorphin production reduced to the point that, when withdrawal symptoms arise, endorphins that would have kicked in to reduce pain are not able to do so, making the symptoms feel even worse than they otherwise would be. When the pain of withdrawal becomes particularly bad, the person may desperately crave more heroin in order to relieve the pain. These symptoms also motivate those with heroin dependence to make sure that they can get their next dose; they may steal or turn to prostitution (with its increased risk of HIV/AIDS) to finance their habit.

Hallucinogens THC, the active ingredient in marijuana, is chemically similar to the type of neurotransmitters known as *cannabinoids* (*anandamide* is one such cannabinoid),

and it activates the dopamine reward system. For instance, in rats, cannabinoids trigger dopamine release in the nucleus accumbens (Tanda, Pontieri, & Di Chiara, 1997). People who began abusing marijuana at an early age have atrophy of brain areas that contain many receptors for cannabinoids (DeBellis et al., 2000; Ernst & Chefer, 2001; Wilson et al., 2000), especially the hippocampus and the cerebellum. Atrophy of the hippocampus can explain why chronic marijuana users develop memory problems, and atrophy of the cerebellum can explain why they develop balance and coordination problems. These brain areas are illustrated in Figure 9.10. Cannabinoids also modulate other neurotransmitters and affect pain and appetite (Wilson & Nicoll, 2001).

Dissociative Anesthetics PCP and ketamine alter the distribution in the brain of glutamate, a fast-acting excitatory neurotransmitter. Excitatory neurotransmitters induce brain activity and may underlie the violent, impulsive effects of these drugs. In addition, glutamate is involved in memory, pain perception, and responding to the environment (NIDA, 2007f). Glutamate can be toxic; it actually kills neurons if too much is present. Thus, by increasing levels of glutamate, dissociative anesthetics may, eventually, lead to cell death in brain areas that have receptors for this neurotransmitter—which would explain the memory and other cognitive deficits observed in people who abuse these drugs.

Genetics of Other Types of Substance Abuse

The genetic bases of abuse of other types of substances have not been studied in as much depth as those of alcohol abuse. However, one twin study of cannabis dependence (Lynskey et al., 2002) estimated that genes account for 45% of the variance in vulnerability to cannabis dependence, shared environmental factors account for 20%, and non-shared environmental factors account for the remaining 35%. Consistent with these findings, Tsuang and colleagues (2001) concluded from a study of over 3,330 male twins that genes, shared environment, and unique environmental factors all affect substance abuse (of illicit drugs).

Psychological Factors

Abuse of these other types of substances is affected by most of the same psychological factors that influence abuse of stimulants and depressants (see the starred items in Table 9.7): observational learning, operant conditioning, and classical conditioning all contribute to substance abuse as a maladaptive coping strategy. We examine here the unique aspects of classical conditioning associated with heroin abuse and dependence.

Classical conditioning can help explain how some accidental heroin “overdoses” occur (Siegel, 1988; Siegel et al., 2000). The quotation marks around the word *overdoses* are meant to convey that, in fact, the user often has not taken more than usual but has taken a usual dose in the presence of novel stimuli (Siegel & Ramos, 2002). If a user normally takes heroin in a particular place, such as the basement of the house, he or she develops a conditioned response to being in that place: The brain triggers physiological changes to get ready for the influx of heroin, activating compensatory mechanisms to dampen the effect of the about-to-be-taken drug. This response creates a tolerance for the drug, but—and here’s the most important point—only in that situation. The stimuli in a “neutral” setting (not associated with use of the drug), such as a bedroom, have not yet become paired with taking heroin—and hence the brain does not trigger these compensatory mechanisms before the person takes the drug. In this case, the conditioned stimulus (e.g., the basement) is not present to elicit the compensatory response. And, without this response, the same dose of heroin can have a greater effect if taken in the bedroom than it would have if taken in the basement, causing an “overdose.”

Figure 9.10

9.10 ► Marijuana's Effects on the Brain

When marijuana is smoked, its active ingredient, THC, attaches to cannabinoid receptors in numerous brain areas, including in the nucleus accumbens, which is part of the dopamine reward system. People who began abusing marijuana at an early age eventually have atrophy of brain areas that have many cannabinoid receptors, especially the hippocampus and cerebellum.

Social Factors

The social factors that are commonly associated with abuse of or dependence on stimulants and depressants also apply to narcotic analgesics, hallucinogens, and dissociative anesthetics (see the starred items in Table 9.8). These include dysfunctional family interactions and a higher proportion of substance-abusing peers, which in turn affects the perceived norms of substance use and abuse (Kuntsche et al., 2009). Moreover, economic hardship and unemployment are associated with substance abuse and dependence, perhaps because of chronic stress that arises from economic adversity as well as increased exposure to substance abuse.

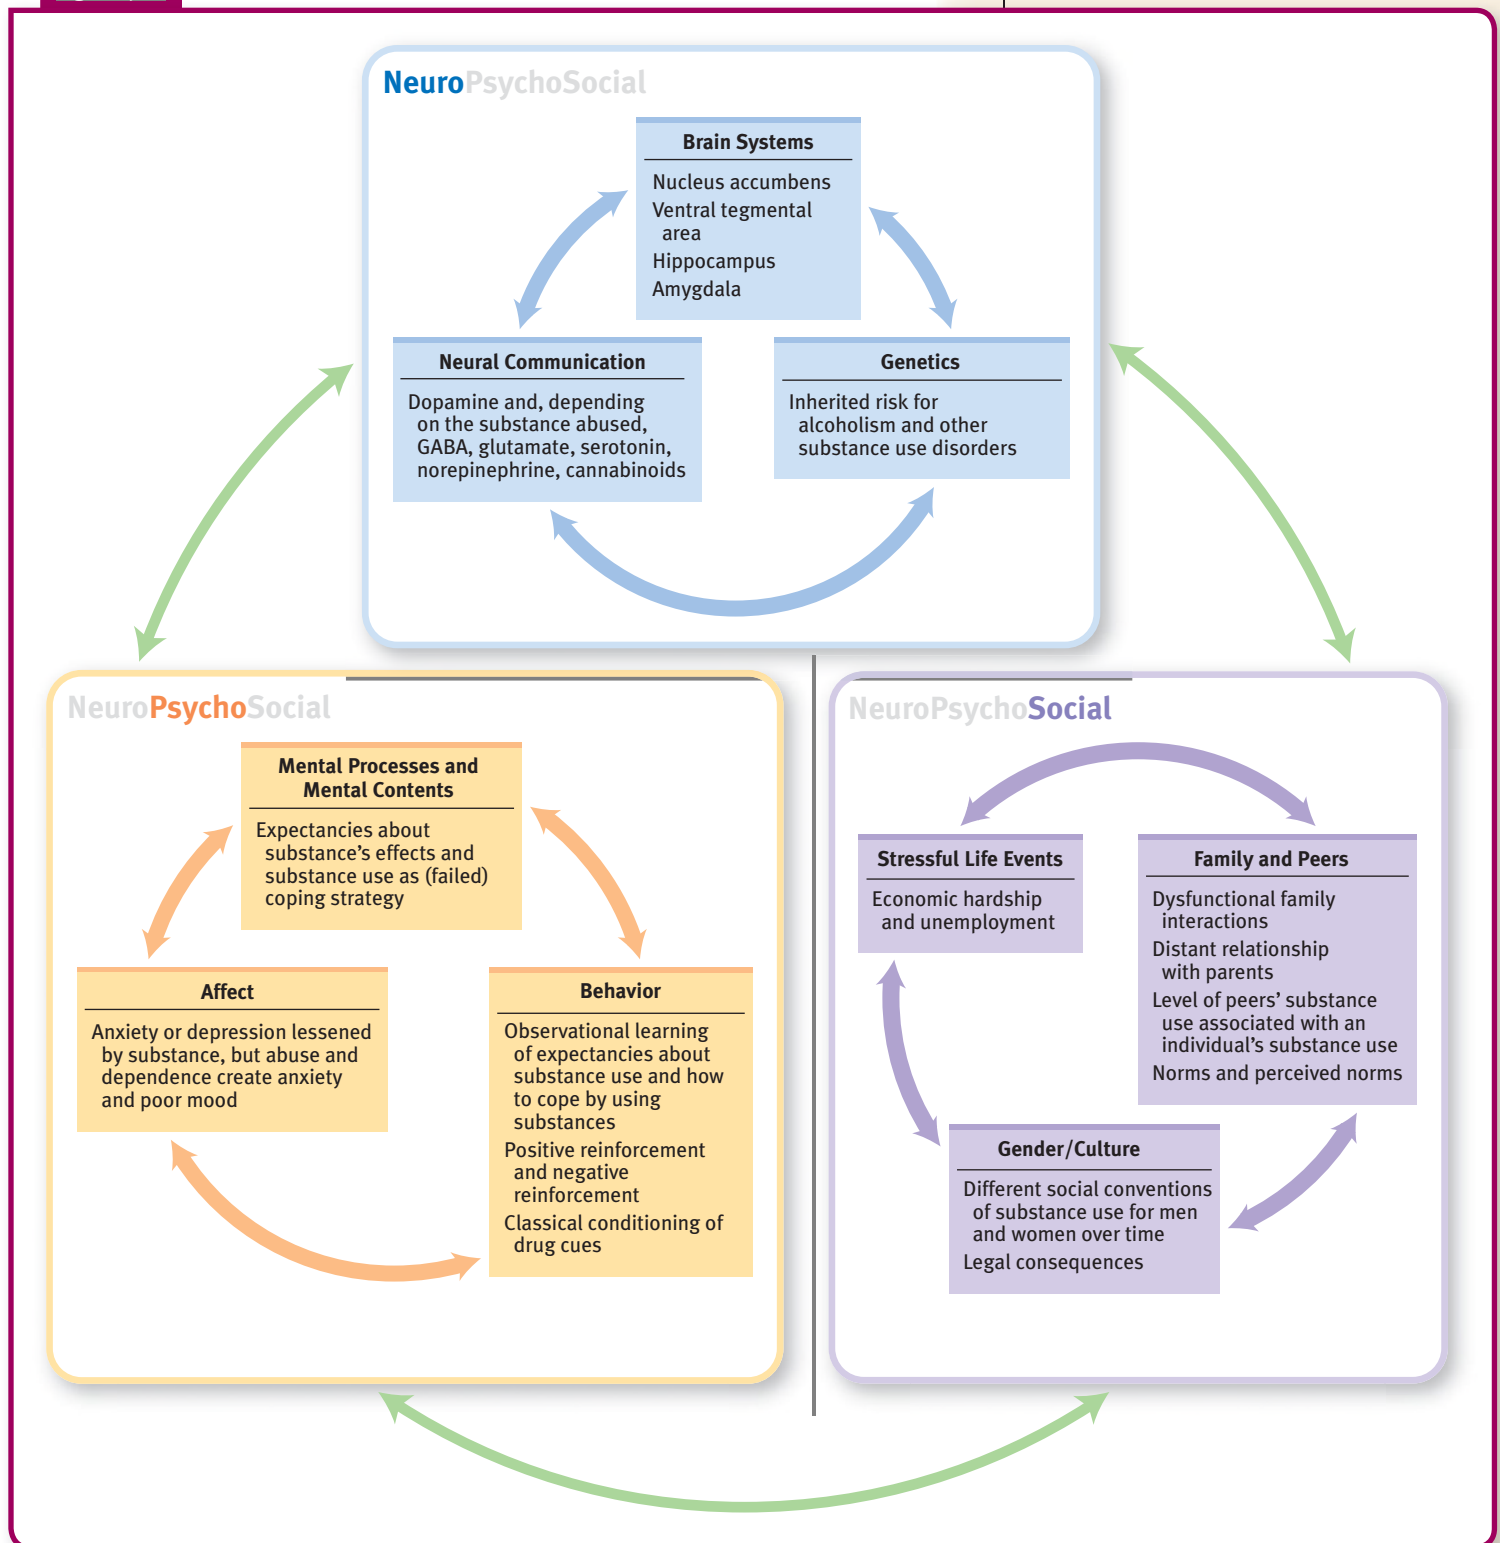

FEEDBACK LOOPS IN ACTION: Understanding Substance Use Disorders

The neurological, psychological, and social factors that contribute to substance abuse and dependence in general do not act in isolation but affect each other through various feedback loops (see Figure 9.11). For example, in one study, researchers examined children who did not have a substance use disorder, but whose parents had a history of either alcohol or drug dependence (Elkins et al., 2004). Children from the two types of families had different characteristics. Children whose parents had a history of *alcohol* dependence were more likely to have negative emotions such as sadness and anger and to be aggressive. They were also more likely to feel alienated and to react more strongly to stressful events (psychological factors). In contrast, children whose parents had a history of *drug* dependence reported lower self-control and showed lower levels of the temperamental trait *harm avoidance*; people who are low in harm avoidance are less responsive to signals of possible punishment.

One possible explanation for these results is that these personality differences in the children arose because of neurological differences (genetic or temperamental) between the two groups of parents. However, the researchers found that differences in the two groups resulted from all three types of factors and from interactions among them via feedback loops. For instance, some neurological factors tend to have a direct relationship with substance abuse and dependence: The effects that a given substance produces in the brain can be directly influenced by specific genes and an individual's prior exposure to the drug—either in the mother's womb or after birth. These factors affect everyone, although in different ways. As a specific example noted earlier in this chapter, participants who rated an injection of Ritalin as pleasant had fewer dopamine receptors, which suggests a neurological—and possibly genetic—vulnerability to stimulant abuse. But neurological factors, such as genes and their influence on temperament, can also have indirect effects: Someone who is high in the trait of novelty seeking, for instance, may be more willing to try a drug than someone low in that trait (DeJong, 2001). However, being high in novelty seeking doesn't necessarily *lead* to substance use and abuse; after all, most people who score high in this temperament do not abuse substances. As another example, some people have a temperament that leads them to be more responsive to reward (and to a drug's rewarding effects) than others are. In turn, this temperament leads them to be more easily affected by operant conditioning when using a drug (psychological factor): Someone who is more responsive to reward is likely to find a given blood alcohol concentration more enjoyable than might someone who is less responsive to reward.

And psychological factors and social factors also play a role in the development of substance use disorders. For instance, as noted previously, experiencing child abuse, neglect, or another significant social stressor increases the risk for substance abuse (Compton et al., 2005), although it does not inevitably lead to it. Moreover, as we saw for alcohol use, peer and family interactions and culture (social factors) help determine perceived social norms, which in turn alter a person's

Figure 9.11

9.11 ► Feedback Loops In Action:
Substance Use Disorders

expectations about the effects of taking a substance and his or her willingness to try the substance or continue to use it (psychological factor). And once a person has tried a drug, its specific neurological effects and other consequences of its use—such as whether the experience of taking the drug is reinforced and how friends respond to the drug use (psychological and social factors)—will affect how likely the person is to continue using it. For instance, the Beatles took Preludin because they were handed the pills and everyone around them was taking them (social factor). Once they took the pills, they found that they could play longer and stay up later (neurological factor), which was reinforcing (psychological factor). In turn, the band members developed expectations about Preludin's effects and were motivated to take it again (psychological factor).

Once someone's drug use reaches a level where tolerance and withdrawal occur, the unpleasant consequences of withdrawal and cravings (neurological and psychological factors) increase the risk of continued dependence. And when a former abuser goes into a social situation in which he or she previously abused drugs, the cues of that environment—the people, the bar, the drug paraphernalia—trigger cravings for the drug. What's more, larger social forces (such as economic stressors or family or community violence) can act to heighten the negatively reinforcing aspects of substance abuse as a way to cope with difficult circumstances.

Key Concepts and Facts About Other Abused Substances

- Narcotic analgesics, also called opioids, can dull pain and decrease awareness. Continued opioid use quickly leads to tolerance and withdrawal, as well as compulsive drug-related behaviors. Heroin is an opioid. Opioids activate the dopamine reward system. They also depress the central nervous system and decrease endorphin production, thereby reducing the body's inherent ability to relieve pain. Using an opioid and a depressant at the same time is potentially lethal.
- Hallucinogens include LSD, mescaline, psilocybin, and marijuana. Hallucinogens have unpredictable effects, which depend in part on the user's expectations and the context in which the drug is taken. People can have a "bad trip" when using LSD and can experience flashbacks long after the drug wears off. LSD affects serotonin functioning.
- Although the effects of marijuana are more subtle, abuse of or dependence on this hallucinogen affects motivation, learning, and memory. The active ingredient in marijuana—THC—appears to have an effect on the brain similar to that of cannabinoids, and activates the dopamine reward system. Chronic marijuana users may develop withdrawal.
- Dissociative anesthetics (sometimes referred to as "club drugs") are so named because they induce a sense of dissociation and cause anesthesia. They depress the central nervous system and affect glutamate activity. Dissociative anesthetics include PCP and ketamine. Use and abuse of this type of drug impairs cognitive functioning and can lead to violent behavior.
- Genes may predispose some people to develop abuse of or dependence on these substances.
- Psychological factors related to substance use disorders include observational learning of what to expect from taking the drugs and of using the drugs as a coping strategy. Classical conditioning of stimuli related to drug use can lead to cravings and can play a role in building tolerance (and hence overdoses are more likely when those cues are not present). In addition, the disorders may arise in part from operant conditioning (reinforcement of the effects of the drug).
- Social factors related to substance use disorders include the individual's relationships with family members, peers' use of substances, cultural norms and perceived norms about appropriate and inappropriate use of substances, and socioeconomic factors.
- These factors form feedback loops: Genes influence temperament, which in turn influences an individual's choice of peer group and willingness to experiment with (and continue to use) drugs. The relationship also works the other way: Social factors can influence what peer groups are available to an individual, which in turn influences the models he or she observes of how to cope and of the perceived norms of substance use. These factors then affect an individual's substance use, which leads to specific neurological effects (including tolerance and withdrawal), which further influence substance use behavior.

Making a Diagnosis

- Reread Case 9.6, and determine whether or not the young man's symptoms meet the criteria for abuse of or dependence on PCP. Specifically, list which criteria apply and which ones do not. If you would like more information to determine whether he is dependent on PCP, what information—specifically—would you want, and in what ways would the information influence your decision?

Treating Substance Use Disorders

Three of the four Beatles were known to have at least one type of substance dependence: George Harrison on nicotine (cigarettes), Ringo Starr on alcohol (for which he received treatment), and John Lennon on alcohol and heroin. It is not known whether any of the Beatles (other than Starr) received professional treatment for their abuse or dependence. Lennon reportedly quit using heroin all at once—*cold turkey*—without medical supervision.

We begin by considering the goals of treatment—what the best outcomes can be. Then we examine the treatments that target neurological, psychological, and social factors, and, when appropriate, note the use of specific treatments for particular types of substance abuse or dependence. However, as we shall see, many treatments that target psychological and social factors can effectively treat abuse of and dependence on more than one type of substance. Unfortunately, though, relapse rates after any type of treatment are high enough that people with substance abuse and dependence may need repeated episodes of treatment (NIDA, 2008f).

Goals of Treatment

Treatments for substance abuse and dependence can have two different ultimate goals. One goal is abstinence—leading the person to stop taking the substance entirely. When the goal of treatment is abstinence, relapse rates tend to be high (up to 60% by some estimates), particularly among patients with comorbid disorders (Brown & D’Amico, 2001; Curran et al., 2000; NIDA, 1999, 2008f). To help patients achieve abstinence, pharmaceutical companies have focused their efforts on developing two types of medications: (1) those that minimize withdrawal symptoms, and (2) those that block the “high” if the substance is used, thereby leading to extinction of the conditioned responses arising from substance abuse and dependence.

Given that abstinence-focused treatments have not been as successful as hoped, an alternative goal of treatment has emerged, which focuses on *harm reduction*—trying to reduce the harm to the individual and society that may come from substance abuse and dependence. For example, needle exchange programs give users a clean needle for each heroin injection, which decreases the transmission of HIV/AIDS because users don’t need to share needles that may be contaminated with HIV. In some cases, harm reduction programs may also seek to find a middle ground between abuse and abstinence: controlled drinking or drug use. For those with symptoms of tolerance and withdrawal, which indicate dependence on alcohol or a drug, such a middle ground may be more difficult to achieve, however (Rosenberg & Melville, 2005). In the United States, most treatment programs have the goal of abstinence.

Targeting Neurological Factors

Treatments that are directed toward neurological factors approach substance use disorders as diseases, and thus select medications as the treatment. In this section we consider detoxification and then turn to medications used to treat abuse of and dependence on stimulants, depressants, narcotic analgesics, and hallucinogens.

Detoxification

Detoxification (also referred to as *detox*) is medically supervised withdrawal for those with substance dependence. Detoxification may involve a gradual decrease in dosage over a period of time to prevent potentially lethal withdrawal symptoms, such as seizures. People with alcohol, benzodiazepine, barbiturate, or opioid dependence should be medically supervised when they stop taking the substance particularly if they were using high doses. Use of other drugs, such as nicotine, cocaine, marijuana, and other hallucinogens, can be stopped abruptly without fear of medical

Two alternative goals guide treatments for substance abuse and dependence. One goal is abstinence—completely stopping the use of the substance. The other goal is harm reduction—lessening the harmful *effects* related to the substance abuse or dependence (for example, lowering the incidence of HIV/AIDS among heroin users by discouraging needle sharing).

Jack Merritt / Alamy

Detoxification

Medically supervised withdrawal for those with substance dependence; also referred to as *detox*.

problems, although the withdrawal symptoms may be unpleasant. John Lennon was not medically supervised when he stopped using heroin, and he described his disturbing withdrawal experience in his song “Cold Turkey”: “Thirty-six hours/Rolling in pain/Praying to someone/Free me again.” Because substance abuse and dependence cause permanent brain changes (which are evident even years after withdrawal symptoms have ceased; Hyman, 2005), O’Brien (2005) proposed that treatment for substance use and dependence should not end with detox, but rather should be a long-term venture, similar to long-term treatment for chronic diseases such as diabetes and hypertension.

Medications

Medications that treat substance abuse or dependence operate in any of several ways: (1) They interfere with the pleasant effects of drug use; (2) they reduce the unpleasant effects of withdrawal; or (3) they help maintain abstinence. Because of the high relapse rate among those who are dependent on a substance, however, medications should be supplemented with other relapse prevention strategies (O’Brien, 2005), described in the sections on treatments targeting psychological and social factors. We now turn to consider medications for specific types of drug abuse and dependence.

Stimulants

Of all drugs, stimulants have the most direct effects on the dopamine reward system. Unfortunately, medications that modify the action of the dopamine receptors per se (in the dopamine reward system) have not yet been developed. However, some medications do affect the functioning of dopamine. For example,

a medication that helps people stop smoking is *bupropion* (marketed as Zyban), which acts by affecting the functioning of several neurotransmitters—including dopamine. Bupropion can help to decrease cravings, both for nicotine and for methamphetamines (Killen et al., 2006; Newton et al., 2006). Alternatively, smoking can be treated by delivering nicotine through a form other than cigarettes, such as via skin patches, chewing gum, nasal inhalers, or sprays. These types

Nicotine replacement therapy—via skin patches, gum, nasal sprays, and inhalers—provides the user with nicotine in a less harmful manner than smoking cigarettes.

of treatments are commonly referred to as *nicotine replacement therapy* because they replace a more harmful method of nicotine intake (smoking) with a less harmful method. After a period of time, the user tapers off nicotine by using less of the replacement form.

Depressants

Medication for dependence on depressants (such as alcohol) minimizes withdrawal symptoms by substituting a less harmful drug in the same category for the more harmful one. For example, longer-acting benzodiazepines, such as Valium, may be substituted for alcohol or other depressants.

Disulfiram (**Antabuse**), a medication for treating alcohol abuse and dependence, relies on a different approach. Antabuse causes violent nausea and vomiting when it is mixed with alcohol. When an alcoholic takes Antabuse and then drinks alcohol, the resulting nausea and vomiting should condition the person to have negative associations with drinking alcohol. When Antabuse is taken consistently, it leads people with alcohol dependence to drink less frequently, even though it does not make them more likely to become totally abstinent (Fuller et al., 1986; Sereny et al., 1986). Antabuse may also be effective in treating cocaine dependence (Baker, Jallow, & McCance-Katz, 2007; Carroll et al., 2004). However, many patients choose to stop taking Antabuse instead of giving up drinking alcohol (Suh et al., 2006).

Antabuse

A medication for treating alcohol abuse and dependence that induces violent nausea and vomiting when it is mixed with alcohol.

Naltrexone (reVia) is another medication used to treat alcohol abuse; after detox, it can help maintain abstinence. Naltrexone indirectly reduces activity in the dopamine reward system, making drinking alcohol less rewarding (O'Malley et al., 1992); it is the most widely used medication to treat alcoholism in the United States, and it has minimal side effects. Another medication, *acamprosate*, is more popular in Europe; acamprosate reduces cravings and acts by affecting a different type of receptors (NMDA receptors; Johnson & Ait-Daoud, 2000; Tomkins & Sellers, 2001). Researchers found that a combination of naltrexone and acamprosate is more effective in preventing relapse among those in recovery from alcohol abuse than is either drug alone (Brady, 2005; Kiefer et al., 2003).

Finally, people with alcohol dependence who are undergoing detox may develop seizures; to prevent seizures and decrease symptoms of DTs, patients may be given benzodiazepines, along with the beta-blocker *atenolol*. However, a patient with DTs should be hospitalized (Arana & Rosenbaum, 2000).

Narcotic Analgesics

Medications that are used to treat abuse of or dependence on narcotic analgesics are generally chemically similar to the drugs but that reduce or eliminate the “high”; treatments with these medications seek harm reduction because the medications are a safer substitute. For instance, patients with heroin dependence may be given *methadone*, a synthetic opiate that binds to the same receptors as heroin. For about 24 hours after a current or former heroin user has taken methadone, taking heroin will not lead to a high because methadone prevents the heroin molecules from binding to the receptors. Methadone also prevents heroin withdrawal symptoms and cravings (NIDA 2007c). Although patients on methadone are likely to abstain from using heroin, they are still using a substance, and so methadone doesn't promote complete abstinence, but rather heroin abstinence.

Because methadone can produce a mild high and is effective for only 24 hours, patients on methadone maintenance treatment generally must go to a clinic to receive a daily oral dose, a procedure that minimizes the sale of methadone on the black market. Methadone blocks only the effects of heroin, so those taking it might still use cocaine or alcohol to experience a high (El-Bassel et al., 1993). Another medication, *LAAM* (levo-alpha-acetyl-methadol), blocks the effects of narcotic analgesics for up to 72 hours (and so requires trips to a clinic only a few times a week) and does not produce a high. However, LAAM can cause heart problems and so is only prescribed for patients with a dependence on a narcotic analgesic for whom other treatments have proven inadequate.

Methadone and LAAM are generally available only in drug treatment clinics. In contrast, those seeking medication to treat abuse of or dependence on narcotic analgesics can receive a prescription for *buprenorphine* (Subutex) in a doctor's office. Buprenorphine is also available in combination with *naloxone* (Suboxone). In either preparation, buprenorphine has less potential for being abused than methadone because it does not produce a high. Treatment of opiate dependence with substitution medications, such as methadone, is generally more successful than promoting abstinence (D'Ippoliti et al., 1998; Strain et al., 1999; United Nations International Drug Control Programme, 1997).

Naltrexone is also used to treat alcohol dependence and often in combination with buprenorphine, to treat opiate dependence (Amass et al., 2004). Naltrexone is generally most effective for those who are highly motivated and willing to take medication that blocks the reinforcing effects of alcohol or opioids (Tomkins & Sellers, 2001).

Finally, the beta-blocker *clonidine* (Catapres) may help with withdrawal symptoms (Arana & Rosenbaum, 2000). A summary of medications used to treat substance abuse and dependence is found in Table 9.10.

Table 9.10 ▶ Medications Used to Treat Withdrawal and Promote Maintenance in People with Substance Use Disorders

Class of Drugs	To Treat Withdrawal	To Promote Maintenance
Stimulants: Nicotine	<i>Nicotine products</i> (chewing gum, patch), <i>bupropion</i> (Zyban)	
Depressants	Longer-acting <i>depressants</i> (such as Valium) that block withdrawal symptoms	<i>Antabuse, acamprosate, naltrexone</i>
Narcotic Analgesics	<i>Methadone, buprenorphine, clonidine</i>	<i>Methadone</i> (technically, promotes maintenance by binding to receptors that would otherwise bind with heroin), <i>buprenorphine, LAAM, naltrexone</i>

Hallucinogens

Those who abuse LSD and want to quit can generally do so without withdrawal symptoms or significant cravings. Thus, marijuana is the only substance in this category that has been the focus of research on treatment, which generally targets psychological factors and social factors, not neurological ones (McRae, Budney, & Brady, 2003).

Targeting Psychological Factors

Treatments that target psychological factors focus on several elements: (1) increasing a user's motivation to cease or decrease substance use, (2) changing the user's expectations of the drug experience, (3) increasing the user's involvement in treatment, and (4) decreasing the (classically and operantly) conditioned behaviors associated with use of the drug.

Motivation

For those with substance abuse or dependence, stopping or decreasing use is, at best, unpleasant and, at worst, very painful and extremely aversive. Therefore, the user's motivation to stop or decrease strongly affects the ultimate success of any treatment.

Stages of Change

Extensive research has led to a theory of treatment that posits different stages of readiness for changing problematic behaviors of the sort associated with substance abuse and dependence. Research on this theory of **stages of change** has also led to methods that promote readiness for the next stage (Prochaska & DiClemente, 1994). Whereas most other treatments rely on a dichotomous view of substance use—users are either abstinent or not—this approach rests on the idea of intermediate states between these two extremes; the five stages of readiness to change are as follows:

1. **Precontemplation.** The user does not admit that there is a problem and doesn't intend to change. A temporary decrease in use in response to pressure from others will be followed by a relapse when the pressure is lifted.
2. **Contemplation.** The user admits that there is a problem and may contemplate taking action. However, no actual behavioral change is undertaken at this stage; behavior change is something considered for the future. People with substance abuse and dependence may never get past this stage.
3. **Preparation.** The user is prepared to change. He or she has a specific commitment to change, a plan for change, and the ability to adjust the plan of action

Stages of change

A series of five stages that characterizes how ready a person is to change problematic behaviors: precontemplation, contemplation, preparation, action, and maintenance.

and intends to start changing the substance using behavior within a month. The user is very aware of the abuse, how it reached its current level, and available solutions. Although users in this stage are prepared to change, some are more ambivalent than others and may not implement the intended changes, essentially reverting to the contemplation stage.

4. **Action.** The user actually changes his or her substance use behavior and environment. At this stage, others most clearly perceive the user's intentions to stop or decrease substance use; it is during this stage that family members and friends generally offer the most help and support.
5. **Maintenance.** The user builds on gains already made in stopping or decreasing substance use and tries to prevent relapses. Former substance users who do not devote significant amounts of energy and attention to relapse prevention are likely to relapse all the way to the contemplation—or even the precontemplation—stage. Help and support from others, although important for maintenance, are usually less forthcoming at this stage; friends and family members usually mistakenly think that because the substance abuse has stopped or diminished, the former user is finished taking action. In fact, the former user must *actively* prevent relapses, and help and support from friends and family members is very important in this stage.

This description of the five steps suggests a lock-step model: Each stage has discrete tasks that allow entry to the next in a linear progression. Research, however, suggests that the stages are not mutually exclusive (Litrell & Girvin, 2002). For example, most people in the stage of action have occasional relapses and engage in the unwanted behavior, but they do not totally relapse into the old patterns. Also, uninterrupted forward progress is not the most typical path. People often regress before moving forward again. For example, only 5% of smokers who think about quitting go through all the stages of change within 2 years without a relapse (Prochaska, Velicer, et al., 1994).

Motivational Enhancement Therapy

Motivational enhancement therapy (also referred to as *motivational interviewing*) is specifically designed to boost patients' motivation to decrease or stop substance use (Hettema, Steeler, & Miller, 2005; Miller & Rollnick 1992). In this therapy, the patient (referred to as client in the original transcript) sets his or her own goals regarding substance use, and the therapist points out discrepancies between the user's stated personal goals and his or her current behavior. The therapist then elicits the user's desire to meet the goals, overriding the rewarding effects of drug use. Therapists using motivational enhancement therapy do not dispense advice or seek to increase any specific skills; rather, they focus on increasing the motivation to change drug use, discussing both positive and negative aspects of drug use, reasons to quit, and how change might begin (Miller, 2001). Below is a transcript from a motivational interviewing session that illustrates how such treatment is used.

Client: So I see I need to cut down using cocaine, but it's not as big a deal as everyone seems to think. My husband nags me about it all the time, but it's not like he says.

Interviewer: Well, let me ask you this: What are the good things about using cocaine?

Client: What?

Interviewer: I'm curious what's good about it.

Client: You mean like . . .?

Interviewer: What are the benefits in using it?

Client: (pause) There is nothing like the high I get from a snort.

Interviewer: (making a list) One good thing is the feeling that comes when you're high. Tell me more about that.

Client: Total euphoria. I feel like I can accomplish anything I put my mind to. I'm Superwoman. Nothing bothers me, not even my whiny kids.

Motivational enhancement therapy

A form of treatment specifically designed to boost a patient's motivation to decrease or stop substance use by highlighting discrepancies between stated personal goals related to substance use and current behavior; also referred to as *motivational interviewing*.

Interviewer: A feeling of total power and exhilaration, then.

Client: Yeah, but when I come down I pay for it. It's a real downer, and it lasts forever. Then I just want to get high again, and the whole thing is a vicious cycle. And my kids are still whining.

Interviewer: So in the short run, it's a big payoff, but in the long term the cost is too much.

Client: Yeah, I've been thinking that I should cut it way back.

Interviewer: You might want to change, but you're not sure.

Client: No, I know I need to do something.

Interviewer: You've already thought about changes you might make.

(Moyers, 2003, pp. 141–142)

Studies have shown that this treatment is more successful when patients have a positive relationship with their therapist and are at the outset strongly motivated to obtain treatment (Etheridge et al., 1999; Joe, Simpson, & Broome, 1999). As with most treatments, the beneficial effects of motivational interviewing tend to fade over the course of a year (Hettema, Steele, & Miller, 2005).

Cognitive-Behavior Therapy

Cognitive-behavior therapy (CBT) for substance abuse focuses on three general themes:

1. understanding and changing thoughts, feelings, and behaviors that lead to substance use (*antecedents*);
2. understanding and changing the *consequences* of the substance use; and
3. developing *alternative behaviors* to substitute for substance use (Carroll, 1998; Marlatt & Gordon, 1985).

Behavioral treatment may focus in particular on decreasing the positive consequences of drug use and on increasing the positive consequences of abstaining from drug use (referred to as *abstinence reinforcement*). As patients are able to change these consequences, they should be less motivated to abuse the substance. These principles may be used more generally for *contingency management*, in which reinforcement is contingent on the desired behavior occurring or the undesired behavior not occurring (Stitzer & Petry, 2006).

These principles have been applied to treatments for abuse of a variety of types of substances, including heroin and cocaine (Higgins et al., 1993; Higgins & Silverman, 1999). The desired behavior (such as attendance at treatment sessions or abstinence from using cocaine, as assessed by urine tests) is reinforced with one or more of these consequences:

- monetary vouchers, the value of which increases with continued abstinence (Jones et al., 2004; Silverman et al., 1999, 2001, 2004);
- decreasing the frequency of mandatory counseling sessions if treatment has been court ordered;
- more convenient appointment times; or
- being allowed to take home a small supply of methadone (requiring fewer trips to the clinic) for those being treated for heroin abuse.

Positive incentives (obtaining reinforcement for a desired behavior) are more effective than negative consequences (such as taking away privileges) in helping patients to stay in treatment and in decreasing substance use (Carroll & Onken, 2005). The cost of providing such rewards can be high, and relapse often increases once rewards are discontinued, which limits the practicality and effectiveness of abstinence reinforcement as a long-term treatment (Carroll & Onken, 2005). Figure 9.12 illustrates the effectiveness of monetary vouchers in promoting abstinence among cocaine users.

Once the patient has stopped abusing the substance, behavioral treatment may focus on preventing relapse by extinguishing the conditioned response

Figure 9.12

9.12 ► Abstinence Reinforcement Among Cocaine Users

This graph illustrates the results of a 21-week study with cocaine users on the effects of reinforcing abstinence with vouchers. When patients' abstinence was reinforced with vouchers—compared to patients in a control group whose abstinence was not reinforced—they were more likely to stop using the drug. The abstinence reinforcement group and the control group were significantly different in their cocaine use in weeks 3–12 of the voucher period and weeks 1 and 4 of the postintervention period.

(including cravings) to drug-related cues (see Chapter 4 for a detailed discussion of extinction). Treatment may also focus on decreasing the frequency or intensity of emotional distress, which can contribute to relapse (Vuchinich & Tucker, 1996). One way treatment can help patients regulate emotional distress is by helping them develop healthier coping skills, which will then increase self-control. Thus, many of the CBT methods used to treat depression and anxiety can be effective here; methods include self-monitoring, cognitive restructuring, problem solving, and various relaxation techniques.

Once (former) users come to understand the antecedents and consequences of their substance use and have developed alternative behaviors, they might be asked to complete a form that contains items like those in Table 9.11—which will help consolidate their ability to make healthier choices and prevent relapse.

Initially, CBT may focus narrowly on the substance use itself—that is, on how the patient copes when he or she has thoughts about using the substance. Later, the treatment expands to focus on related problem areas, such as employment or relationship difficulties.

Twelve-Step Facilitation (TSF)

Twelve-step facilitation (TSF) is based on the twelve steps or principles that form the basis of Alcoholics Anonymous (AA) (see Table 9.12). AA views alcohol abuse as a disease that can never be cured, although alcohol-related behaviors can be modified by the alcoholic's recognizing that he or she has lost control and is powerless over alcohol, turning to a higher power for help, and seeking abstinence. Research suggests that the AA approach can help those who are trying to stop their substance abuse (Laffaye et al., 2008).

AA's groups are leaderless, whereas TSF's groups are led by mental health professionals, whose goal is to help group members become ready to follow the twelve steps of AA. The twelve-step model has been used by those with narcotic abuse and dependence (Narcotics Anonymous, NA) and in numerous inpatient and outpatient treatment programs run by mental health professionals (Ries et al., 2008). Twelve-step facilitation targets *motivation* to adhere to the steps. In essence, its

Table 9.11 ► Decision Monitoring

When making any decision, whether large or small, do the following:

- Consider all the options you have.
- Think about all the consequences, both positive and negative, for each of the options.
- Select one of the options. Pick a safe decision that minimizes your risk of relapse.
- Watch for “red flag” thinking—thoughts like “I have to . . .” or “I can handle . . .” or “It really doesn't matter if . . .”

Practice monitoring decisions that you face in the course of a day, both large and small, and consider safe and risky alternatives for each.

Table 9.12 ▶ Twelve Steps of Alcoholics Anonymous

- (1) We admitted we were powerless over alcohol—that our lives had become unmanageable.
- (2) Came to believe that a Power greater than ourselves could restore us to sanity.
- (3) Made a decision to turn our will and our lives over to the care of God as we understood Him.
- (4) Made a searching and fearless moral inventory of ourselves.
- (5) Admitted to God, to ourselves and to another human being the exact nature of our wrongs.
- (6) Were entirely ready to have God remove all these defects of character.
- (7) Humbly asked Him to remove our shortcomings.
- (8) Made a list of all persons we had harmed, and became willing to make amends to them all.
- (9) Made direct amends to such people wherever possible, except when to do so would injure them or others.
- (10) Continued to take personal inventory and when we were wrong promptly admitted it.
- (11) Sought through prayer and meditation to improve our conscious contact with God as we understood Him, praying only for knowledge of His will for us and the power to carry that out.
- (12) Having had a spiritual awakening as the result of these steps, we tried to carry this message to alcoholics, and to practice these principles in all our affairs.

Source: http://www.aa.org/en_pdfs/smf-121_en.pdf.

goals are like those of motivational enhancement therapy but the enhanced motivation focuses on sticking with a specific type of treatment.

Matching Treatment to Patient

Research sponsored by the National Institute on Alcohol Abuse and Alcoholism studied whether some types of treatments for alcohol abuse and dependence are more effective for certain types of people. That is, the research sought to *match* treatment types and patients. Investigators compared TSF, CBT, and motivational enhancement across variables such as gender, readiness to change, severity of abuse, degree of cognitive impairment, and additional psychiatric problems (Project MATCH Research Group, 1997, 1998). This large study found that patients generally tended to improve regardless of the type of treatment; all three treatments reduced the amount and frequency of drinking as well as of use of other drugs. Patients who were depressed found that treatment improved their mood, and the improved mood lasted for up to a year afterward. No matches were found between types of patients and types of treatments. Studies of treatments for abuse of cocaine have produced similar findings regarding matching (Beck, 1999).

Although studies have not shown a neat match between specific types of patients and specific treatments, two general findings have emerged: (1) For patients who abuse more than one substance, a single treatment program that focuses on polysubstance abuse tends to be more effective than a series of programs that focus on one substance at a time. (2) Patients who have substance abuse or dependence and another psychiatric disorder (which is true of many abusers) fared better when the other disorder was also treated.

Targeting Social Factors

Treatments that target social factors aim to change interpersonal and community antecedents and consequences of substance abstinence and use. Antecedents might be addressed by decreasing family tensions, increasing summer employment among teens, and decreasing community violence. Consequences might be addressed by increasing community support for abstinence and providing improved housing or employment opportunities for reduced use or for abstinence.

Residential Treatment

Some people who seek treatment for substance abuse may need more intensive help, such as the assistance that can be found in residential treatment, which provides a round-the-clock therapeutic environment (such as the Betty Ford Center in California). Because it is so intensive, residential treatment can help an individual more rapidly change how he or she thinks, feels, and behaves; some residential treatment programs have a spiritual component. Depending on the philosophy of the program, various combinations of methods—targeting neurological, psychological, and social factors—may be available.

Community-Based Treatment

Treatments that target social factors are usually provided in groups. One approach focuses on providing group therapy, which typically take place in residential programs, day-treatment programs (to which patients come during the day to attend groups and receive individual therapy but do not stay overnight), methadone clinics, and drug counseling centers. In addition, there are a number of self-help groups for people with substance abuse.

Group Therapy

CBT may be used in a group format to help those with substance abuse. The group provides peer pressure and support for abstinence (Crits-Christoph et al., 1999). Moreover, members may use role-playing to try out new skills, such as saying “no” to friends who offer drugs. Other types of groups include social-skills training groups, where members learn ways to communicate their feelings and desires more

Steven L. Raymer/National Geographic/Getty Images

Various types of treatment for substance use disorders can be offered in the community, including day-treatment programs, methadone clinics (such as the one shown here), group therapy, and self-help groups.

effectively, and general support groups to decrease shame and isolation as members change their substance abuse patterns.

Self-Help Groups

Self-help groups (sometimes called support groups), such as the twelve-step programs of Alcoholics Anonymous and Narcotics Anonymous, hold regular meetings. Attending such a group might supplement other treatment or might be the only treatment a person pursues. As noted earlier, such groups often view belief in God or some other “higher power” as crucial to recovery, and even people who are not religious can improve through AA meetings (Humphreys & Moos, 2007; Moos & Timko, 2008; Timko, DeBenedetti, & Billow, 2006; Winzelberg & Humphreys, 1999). AA also provides social support, both from other group members and a *sponsor*—an individual with years of sobriety who serves as a mentor and can be called up when the newer member experiences cravings or temptations to drink again.

Other self-help organizations, such as Secular Organizations for Sobriety and Women for Sobriety, do not include spirituality or a religious component. Still other organizations offer groups that are led by trained professionals and so are technically not self-help groups; Rational Recovery and Smart Recovery are examples. These are based on cognitive-behavioral principles and do not use a twelve-step approach (Nowinski, 2003).

A meta-analysis showed that attending a self-help group at least once a week is associated with drug or alcohol abstinence (Fiorentine, 1999). Other research confirms that longer participation in AA is associated with better outcomes (Moos & Moos, 2004). Just like group therapy, a self-help group can be invaluable in decreasing feelings of isolation and shame. In general, self-help groups can be valuable sources of information and support, not only for the substance abuser but also for his or her relatives.

Family Therapy

To the extent that family interactions lead to or help sustain substance abuse, changing family patterns of interaction can modify these factors (Saatcioglu, Erim, & Cakmak, 2006; Stanton & Shadish, 1997). Among adolescents treated for substance abuse, outpatient family therapy appears to help them to abstain (Smith et al., 2006; Szapocznik, Hervis, & Schwartz, 2003; Williams & Chang, 2000), which suggests that changes in how parents and adolescents interact can promote and maintain abstinence. In fact, family therapy is usually a standard component of treatment for adolescents with substance use disorders (Austin, Macgowan, & Wagner, 2005). The goals of this type of therapy are tailored to the specific problems and needs of each family, but such therapy typically addresses issues related to communication, power, and control (see the discussion of family therapy in Chapter 4; Hogue et al., 2006).

FEEDBACK LOOPS IN TREATMENT: Substance Use Disorders

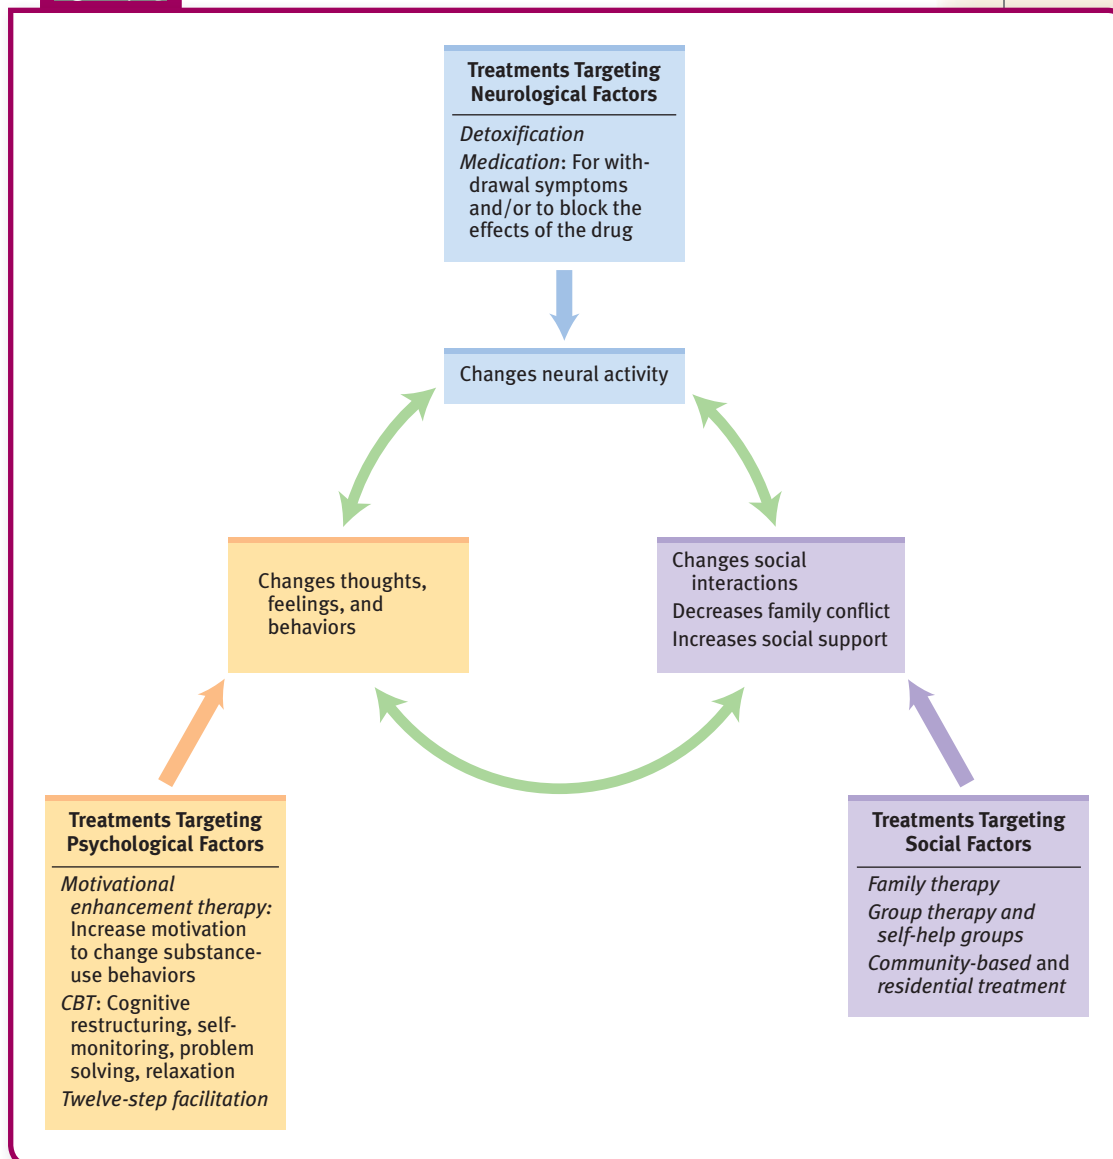

At first glance, using medication to treat substance abuse or dependence might seem like the perfect solution. Substance abuse disrupts neurological factors, and how better to address that disruption than to use another substance? However, for medications to work effectively, they must be taken regularly, which means that users must remain motivated and willing to take them (psychological factor); in addition, the risk of relapse is reduced when a user minimizes contact with people and situations that trigger a desire to use the substance (social factors). Medications may target neural communication and the relevant brain systems, but they don't address the whole person or the person's context: friends, family, work and home environments, and the subculture and community in which the person lives.

The neuropsychosocial approach leads us to categorize the various treatments for substance abuse according to each one's direct target. Regardless of which type of factor is directly targeted, though, how exactly is treatment success determined? The following considerations help to determine whether an intervention was successful. Did the individual:

- complete the treatment, or is he or she still using or abusing the substance? (Is he or she abstinent—yes or no?)
- experience fewer harmful effects from the substance? (Is he or she using clean needles or no longer drinking to the point of passing out?)
- decrease use of the substance? (How much is the person using after treatment?)
- come to behave more responsibly? (Does he or she attend regular AA meetings or get to work on time?)
- feel better? (Is the person less depressed, anxious, “strung out,” or are drug cravings less intense?)
- come to conform to societal norms? (Has he or she stayed out of jail?)

The treatments we've discussed can lead to improvement according to these considerations, but different types of treatments provide different paths toward improvement. Moreover, like most cigarette smokers, many substance abusers may quit multiple times. In addition, like studies of treatments for other types of disorders, studies of treatments for substance abuse have found a dose-response relationship: Longer treatment produces better outcomes than shorter treatment (Hubbard et al., 1989; Simpson, 1984; Simpson, Joe, & Broome, 2002). And for those people who abuse more than one type of substance, treatment is most effective when it addresses the entire set of substances.

The most robust finding about all of the treatments we've discussed is that they work, at least in the short term. Project MATCH showed that CBT, motivational enhancement therapy, and TSF were equally helpful. It also showed that medication and social interventions are effective. Ultimately, all successful treatments address all three types of factors that are identified in the neuropsychosocial approach. When people with substance abuse or dependence first stop abusing the substance, they will experience neurological changes that are, at minimum, uncomfortable (neurological and psychological factors). Moreover, how they think and feel about themselves will change (psychological factor)—from “abuser” or “addict” to “ex-abuser” or “in recovery”. Their interactions with others will change (social factors): Perhaps they will make new friends who don't use drugs, avoid friends who abuse drugs, behave differently with family members (who in turn may behave differently toward them), perform better at work, or have fewer run-ins with the law. Other people's responses to them will also affect their motivation to continue to avoid using the substance and endure the uncomfortable withdrawal effects and ignore their cravings. Thus, as usual, treatment ultimately relies on feedback loops among the three types of factors (see Figure 9.13).

Figure 9.13**9.13 ► Feedback Loops in Treating Substance Use Disorders****Key Concepts and Facts About Treating Substance Use Disorders**

- Treatments that focus on neurological factors include detox to help reduce symptoms of withdrawal that come from dependence. Medications may reduce unpleasant withdrawal symptoms or block the pleasant effects of using the substance, which can help maintain abstinence.
- Treatments that target psychological factors, such as motivational enhancement therapy, are designed to motivate people to decrease substance use. CBT addresses antecedents, consequences, and specific behaviors related to substance use. Twelve-step facilitation provides structure and support to help patients to abstain.
- Social factors are targeted by residential treatment and other types of community-based treatment (group therapy and self-help groups), as well as family therapy to address issues of communication, power, and control.

SUMMING UP

Summary of Use, Abuse, and Dependence

The hallmark of substance use disorders is abuse of or dependence on a psychoactive substance. The term *addiction* focuses on the compulsive behaviors related to regular drug taking, but is not used in DSM-IV-TR. *Substance abuse* refers to the pattern of use of a psychoactive substance that leads to harmful effects; *substance dependence* refers to the persistent and compulsive use of a psychoactive substance, despite the ensuing negative consequences. Tolerance and withdrawal are common symptoms of substance dependence.

Researchers have developed two compatible explanations of why substance use may lead to abuse. The common liabilities model focuses on underlying factors that may contribute to a variety of problematic behaviors, including substance abuse. The gateway hypothesis focuses on factors that lead individuals to progress from using entry drugs to using harder drugs.

In DSM-IV-TR, substance abuse and dependence are characterized as discrete categories; some researchers suggest that they may be better conceptualized as being on a continuum. Substance use disorders frequently co-occur with mood disorders (particularly depression), PTSD, schizophrenia, and ADHD. Many people with substance use disorders engage in polysubstance abuse. Cultures can promote or regulate substance use through the use of rituals and penalties.

Thinking like a clinician

Jorge and his friend Rick worked hard and played hard in high school. On weekend evenings, usually their only free time, they'd binge drink, along with others in their group. They went to different colleges. Jorge kept up his "study hard, party hard" lifestyle; Rick didn't do much binge drinking in college, but he started smoking marijuana in the evenings when he was done studying and he'd go dancing on Saturday nights and sometimes take Ecstasy or stimulants. What information would you want to know in order to determine whether Jorge or Rick had a substance use disorder? How would you know whether either was dependent on a substance?

Summary of Stimulants

Stimulants, which increase arousal and brain activity, are the category of psychoactive substances most likely to lead to dependence. Unlike many other types of drugs,

they act directly—rather than indirectly—on the dopamine reward system by binding to dopamine transporters in the synapse. Stimulants include cocaine and crack, amphetamines, methamphetamine, Ritalin, MDMA, and nicotine. Crack use is associated with the most rapid progression to dependence. In high doses, most of these stimulants can cause paranoia and hallucinations. With continued use, stimulants lead to tolerance and withdrawal.

Neurological factors that contribute to abuse of and dependence on stimulants include activation of the dopamine reward system, which involves the nucleus accumbens and the ventral tegmental area.

Psychological factors related to substance use disorders include learning: operant reinforcement of the effects of the drug, classical conditioning of stimuli related to drug use (which leads to cravings), and observational learning of expectancies about both the effects of drugs and the use of them to cope with problems.

Social factors related to substance use disorders include the specific nature of an individual's relationships with family members, socioeconomic factors, and cultural and perceived norms about appropriate and inappropriate use of substances.

Thinking like a clinician

One night before a major class project was due, Sierra had hours of work left to do, and she'd had all the coffee she could stand. She took one of her roommate's Ritalin pills and stayed up all night, completing the project by morning. Sierra gradually got in the habit of using amphetamines to help her stay up late and do course work. After college, Sierra took a job with lots of deadlines and lots of late hours. She continued to use stimulants to help her work, sometimes taking cocaine when she could get it.

At what point does Sierra's use of stimulants become abuse? Does she have a dependence—why or why not? What would be some specific symptoms that would indicate that she was abusing cocaine? What symptoms would you expect to see if Sierra were taking a high dose of stimulants? According to the neuropsychosocial approach, what factors might have led Sierra to abuse stimulants, if she were abusing them?

Summary of Depressants

Depressants decrease arousal, awareness, and nervous system activity level. Depressants include alcohol, barbiturates, and

benzodiazepines. Continued use of depressants leads to tolerance and withdrawal. Some withdrawal symptoms are potentially lethal; people with a dependence on depressants should be medically supervised as they taper off their use of the drug. Using more than one depressant at the same time is also potentially lethal.

Depressants directly affect the GABAergic system, which in turn dampens activity in key brain areas that give rise to anxiety; for this reason, people with anxiety symptoms are more likely than others to abuse depressants. Depressants also indirectly activate the dopamine reward system.

Psychological factors related to depressant abuse and dependence include observational learning to expect specific effects from depressant use and to use depressants as a coping strategy, positive and negative reinforcement of the effects of the drug, and classical conditioning of drug cues that leads to cravings.

Social factors related to abuse of and dependence on depressants include the specific nature of an individual's relationships with family members, peers' use of depressants, norms and perceived norms about appropriate and inappropriate use of depressants, and socioeconomic factors.

Thinking like a clinician

When you see your neighbor in the hallway in the evenings, she sometimes can't seem to walk in a straight line, her speech is slurred, and she reeks of alcohol. She frequently misses when she tries to put her key in the lock and begins giggling. Once you saw her vomit after such an incident. On a few occasions, she hasn't been so obviously "wasted" and has turned to you and roughly said, "What are you staring at?" One time, when you smirked as she tried to put her key in the lock, she came over to you and threatened to "kick your butt." Even during the daytime, though, she's not very nice or friendly.

Do you think your neighbor has a problem with alcohol, and if so, is it abuse or dependence? Why or why not—what supports or refutes the conclusion that she has an alcohol problem? What information would you want to know before making a confident decision? According to the neuropsychosocial approach, what factors might underlie your neighbor's use of alcohol?

Summary of Other Abused Substances

Narcotic analgesics, also called opioids, can dull pain and decrease awareness. Continued

opioid use quickly leads to tolerance and withdrawal, as well as compulsive drug-related behaviors. Heroin is an opioid. Opioids activate the dopamine reward system. They also depress the central nervous system and decrease endorphin production, thereby reducing the body's inherent ability to relieve pain. Using an opioid and a depressant at the same time is potentially lethal.

Hallucinogens include LSD, mescaline, psilocybin, and marijuana. Hallucinogens have unpredictable effects, which depend in part on the user's expectations and the context in which the drug is taken. People can have a "bad trip" when using LSD and can experience flashbacks long after the drug wears off. Although the effects of marijuana are more subtle, abuse of or dependence on this hallucinogen affects motivation, learning, and memory. The active ingredient in marijuana, THC, appears to have an effect on the brain similar to that of cannabinoids, activating the dopamine reward system.

Dissociative anesthetics are so named because they induce a sense of dissociation and cause anesthesia. They depress the central nervous system and affect glutamate activity. Dissociative anesthetics include PCP and ketamine. Use and abuse of this type of drug impairs cognitive functioning, and can lead to violent behavior. Genes may predispose some people to develop abuse of or dependence on these substances.

Psychological factors related to substance use disorders include observational learning, and operant conditioning (reinforcement of the effects of the drug) and classical conditioning of stimuli related to drug use. Social factors related to substance use disorders include the individual's relationship with family members, peers' use of substances, cultural norms and perceived norms, and socioeconomic factors.

Thinking like a clinician

Nat didn't care much for drinking; his drugs of choice were ketamine and LSD. His friends worried about him, though, because every

weekend he'd either be clubbing (and taking ketamine) or tripping on LSD.

What might be some of the sensations and perceptions that each drug induced in Nat, and why might his friends be concerned about him? Suppose he stopped using LSD, but started smoking marijuana daily. What symptoms might he experience, and why might his friends become concerned? If he switched from taking ketamine to snorting heroin before clubbing, what difference might it make in the long term?

How would you determine whether Nat was abusing or was dependent on these substances? What other information might you want to know before making such a judgment? Do you think he might develop withdrawal symptoms—why or why not? If so, which ones? According to the neuropsychosocial approach, what factors might underlie Nat's use of drugs?

Summary of Treating Substance Abuse

Treatments that focus on neurological factors include detox to help reduce symptoms of withdrawal that come from dependence. Medications may reduce unpleasant withdrawal symptoms or block the pleasant effects of using the substance, which can help maintain abstinence.

Treatments that target psychological factors, such as motivational enhancement therapy, are designed to motivate users to decrease substance abuse. CBT addresses antecedents, consequences, and specific behaviors related to substance use. Twelve-step facilitation provides structure and support to help patients abstain. Social factors are targeted by residential treatment and other types of community-based treatment, as well as family therapy to address issues of communication, power, and control.

Thinking like a clinician

Karl has been binge drinking and smoking marijuana every weekend for the past couple of years. He's been able to maintain his job,

but Monday mornings he's in rough shape and sometimes he's had blackouts when he drinks. He's decided that he wants to quit drinking and smoking marijuana, but feels that he needs some help to do so. Based on what you've read in this chapter, what would you advise for Karl and why? What wouldn't you suggest to him as an appropriate treatment and why not?

Eating Disorders

By the time she was 9 years old, Marya Hornbacher developed **bulimia nervosa**, which is an eating disorder characterized by binge eating along with vomiting or other behaviors to compensate for the large number of calories ingested. By the time she reached 15, she had **anorexia nervosa**, an eating disorder characterized by being at least 15% below expected body weight along with using various methods to prevent weight gain. For the next 5 years, she careened from one eating disorder to another. By Hornbacher's own account she had "been hospitalized six times, institutionalized once, had endless hours of therapy, been tested and observed and diagnosed . . . and fed and weighed for so long that I have begun to feel like a laboratory rat" (Hornbacher, 1998, p. 3). At the age of 23, Hornbacher wrote *Wasted: A Memoir of Anorexia and Bulimia* about her experiences with eating disorders, in which she wonders:

Just what was I trying to prove, and to whom? This is one of the terrible, banal truths of eating disorders: when a woman is thin in this culture, she proves her worth, in a way that no great accomplishment, no stellar career, nothing at all can match. We believe she has done what centuries of a collective unconscious insist that no woman can do—control herself. A woman who can control herself is almost as good as a man. A thin woman can Have It All."

(1998, pp. 81–82)

But as Hornbacher points out, eating disorders don't really help anyone have it all. An eating disorder

. . . is an attempt to find an identity, but ultimately it strips you of any sense of yourself, save the sorry identity of "sick." It is a grotesque mockery of cultural standards of beauty that winds up mocking no one more than you. It is a protest against cultural stereotypes of women that in the end makes you seem the weakest, the most needy and neurotic of all women. It is the thing you believe is keeping you safe, alive, contained—and in the end, of course, you find it's doing quite the opposite. These contradictions begin to split a person in two. Body and mind fall apart from each other, and it is in this fissure that an eating disorder may flourish, in the silence that surrounds this confusion that an eating disorder may fester and thrive.

(1998, p. 6)

Follow-up on Marya Hornbacher

Bulimia nervosa

An eating disorder characterized by binge eating along with vomiting or other behaviors to compensate for the large number of calories ingested.

Anorexia nervosa

An eating disorder characterized by being at least 15% below expected body weight along with using various methods to prevent weight gain.

Eating disorders

A category of psychological disorders characterized by abnormal eating and a preoccupation with body image.

Many people in Western culture try to attain or maintain a particular weight by dieting, exercising, or monitoring their food intake. Some of those people have—or will have—an eating disorder. An **eating disorder** is characterized by abnormal eating and a preoccupation with body image. Females make up 90% of those diagnosed with an eating disorder, and so in this chapter, we will refer to an individual with an eating disorder as “she” or “her;” however, the number of males with eating disorders has been slowly increasing (Hudson et al., 2007).

DSM-IV-TR lists two specific eating disorders: *anorexia nervosa* and *bulimia nervosa*. In this chapter, we examine the criteria for and the medical effects of these two disorders, and consider the criticisms of the criteria used to diagnose them. We also discuss research findings that can illuminate why eating disorders arise and the various methods used to treat them.

Anorexia Nervosa

After years of struggling with bulimia, Marya Hornbacher began “inching” toward anorexia; she gradually became significantly underweight by severely restricting her food intake, refusing to eat enough to obtain a healthy weight:

Anorexia started slowly. It took time to work myself into the frenzy that the disease demands. There were an incredible number of painfully thin girls at [school], dancers mostly. The obsession with weight seemed nearly universal. Whispers and longing stares followed the ones who were visibly anorexic. We sat at our cafeteria tables, passionately discussing the calories of lettuce, celery, a dinner roll, rice. We moved between two worlds. When we pushed back our chairs and scattered to our departments, we transformed. I would watch girls who’d just been near tears in the dorm-room mirrors suddenly become rapt with life, fingers flying over a harp, a violin, bodies elastic with motion, voices strolling through Shakespeare’s forest of words.

(Hornbacher, 1998, p. 102).

Hornbacher wanted to be thin, to be in control of her eating, and to feel more in control of herself generally. She began to eat less and less, to the point where she began to pass out at school.

Let’s investigate anorexia nervosa in more detail. In this section we discuss the specific DSM-IV-TR criteria for anorexia nervosa and its subtypes, the various medical consequences of the disorder, and criticisms of the DSM-IV-TR definition of anorexia nervosa.

What Is Anorexia Nervosa?

A key feature of *anorexia nervosa* (often referred to simply as *anorexia*) is that the person will not maintain at least a low normal weight and employs various methods to prevent weight gain (American Psychiatric Association, 2000). Despite medical and psychological consequences of a low weight, those with anorexia nervosa continue to pursue extreme thinness. Unfortunately, anorexia has a high risk of death, though not all by suicide: About 10–15% of people hospitalized with anorexia eventually die as a direct or indirect consequence of the disorder (American Psychiatric Association, 2000; Zipfel et al., 2000).

Anorexia Nervosa According to DSM-IV-TR

To be diagnosed with anorexia nervosa according to DSM-IV-TR, symptoms must meet four criteria:

1. *A refusal to obtain or maintain a healthy weight* (at least 85% of expected body weight, based on age and height).
2. *An intense fear of becoming fat or gaining weight*, despite being significantly underweight. This fear is often the primary reason that the person refuses to attain a healthy weight. Those who have anorexia are obsessed with their body

AP Photo/Ed Andrieski

Individuals with anorexia nervosa have a very low weight and, despite medical consequences, refuse to maintain a healthy weight. This young woman had been on her college swim team when she suffered a heart attack; her anorexia persisted and she was considered to be a danger to herself and banned from campus.

and food, and their thoughts and beliefs about these topics are usually illogical or irrational, such as imagining that wearing a certain clothing size is “worse than death.” Moreover, their feelings about themselves rise and fall with their caloric intake, their weight, or how their clothes seem to fit. If someone with anorexia eats 50 more calories (for comparison, a single pat of butter provides about 35 calories) than she had allotted for her daily intake, she may experience intense feelings of worthlessness. People who suffer from anorexia often deny that they have a problem and do not see their low weight as a source of concern.

3. *Distortions of body image* (the individual’s view of her body). People with anorexia often feel that their bodies are bigger and “fatter” than they actually are (see Figure 10.1).

Figure 10.1

10.1 ► Body Image Distortion With respect to body image, women with anorexia may simply represent an extreme end of “normal” distortions; many other women do not assess their bodies accurately (Thompson, 1990). Here IDEAL is the average figure that women rated as ideal. ATT MEN (“attractive to men”) shows the average figure that women rated as most attractive to men, whereas OTHER illustrates the average figure that men selected as most attractive. THINK depicts the average figure that women thought of as best matching their own, and FEEL depicts the average figure that women felt best matches their own.

Source: Thompson, 1990.

4. *The suppression of menstruation*, called **amenorrhea**, which is diagnosed after three consecutive missed menstrual cycles in females who have already begun menstruating. If a woman must take hormones to menstruate, she is considered to have amenorrhea. For children and adolescents who have not yet begun menstruating, this criterion does not apply. Table 10.1 lists the DSM-IV-TR diagnostic criteria for anorexia; additional facts about anorexia are provided in Table 10.2, and Case 10.1 provides a glimpse of life with anorexia.

Table 10.1 ► DSM-IV-TR Diagnostic Criteria for Anorexia Nervosa

- A.** Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected).
- B.** Intense fear of gaining weight or becoming fat, even though underweight.
- C.** Disturbance in the way in which one’s body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
- D.** In postmenarcheal females [those who have already begun menstruating], amenorrhea, i.e., the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone, e.g., estrogen, administration.)

Source: Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Text Revision, Fourth Edition, (Copyright 2000) American Psychiatric Association.

Amenorrhea

The suppression of menstruation; this condition is diagnosed after three consecutive missed menstrual cycles.

Table 10.2 ▶ Anorexia Nervosa Facts at a Glance**Prevalence**

- In the course of a lifetime, about 1% of females and up to 0.3% of males will develop anorexia (Hoek & van Hoeken, 2003; Hudson et al., 2007).

Comorbidity

- Most studies find that at least half—but as high as 90%—of patients with anorexia have at least one comorbid psychological disorder. The most common types of comorbid disorders are depression, anxiety disorders, and personality disorders (Agras, 2001; Blinder, Cumella, & Sanathara, 2006; Cassin & van Ranson, 2005; Godart et al., 2003; Lucka, 2006).

Onset

- Anorexia typically emerges between the ages of 14 and 18 (American Psychiatric Association, 2000), although the disorder can make its first appearance at an earlier or a later age (Beck, Casper, & Anderson, 1996; Keith & Midlarsky, 2004).

Course

- Anorexia has the highest mortality rate of any psychological disorder—up to 15% (Zipfel et al., 2000). Half of the deaths are from suicide, and the others are from medical complications of the disorder. People with anorexia who also abuse substances have an even higher risk of death (Keel et al., 2003).
- According to some studies, fewer than 50% of those who survive fully recover (Keel et al., 2005; Von Holle et al., 2008), about 33% improve but do not recover, and 20% develop chronic anorexia (Fichter, Quadflieg, & Hedlund, 2006; Steinhausen, 2002); other studies have found higher rates of full recovery (Johnson, Lund, & Yates, 2003; Keski-Rahkonen et al., 2007). Some people with anorexia gain enough weight that they no longer meet the criteria for the disorder, but meet the criteria for bulimia nervosa (Keel et al., 2005).

Gender Differences

- Approximately 75–90% of those with anorexia nervosa are female (Hoek & van Hoeken, 2003; Hudson et al., 2007).

Cultural Differences

- The specific diagnostic criteria stated in DSM-IV-TR do not necessarily apply to all cultures. Many Chinese girls and women with anorexia have not reported the fear of becoming fat that is typical among people with anorexia in Western cultures. Rather, the reasons they give for their minimal food intake are discomfort when eating or the poor taste of the food (Lee & Lee, 1996).
- In the United States, females of black, Hispanic, or Asian background are less likely to be diagnosed with anorexia nervosa than are white females (Alegria et al., 2007; Nicdao, Hong, & Takeuchi, 2007; Striegel-Moore et al., 2003; Taylor et al., 2007).

CASE 10.1 ▶ FROM THE INSIDE: Anorexia Nervosa

Caroline Knapp suffered from both anorexia and alcohol dependence (see the excerpt from her book, *Drinking: A Love Story*, in Chapter 9, Case 9.5). In describing her relationship with food, she noted that people with anorexia nervosa develop bizarre eating habits and a kind of tunnel vision—focusing on food, on eating, and on not eating:

When you're starving . . . it's hard to think about anything else [except eating or not eating. It's] very hard to see the larger picture of options that is your life, very hard to consider what else you might need or want or fear were you not so intently focused on one crushing passion. I sat in my room every night, with rare exceptions, for three-and-a-half years. In secret, and with painstaking deliberation, I carved an apple and one-inch square of cheddar cheese into tiny bits, sixteen individual slivers, each one so translucently thin you could see the light shine through it if you held it up to a lamp. Then I lined up the apple slices on a tiny china saucer and placed a square of cheese on each. And then I ate them one by one, nibbled at them like a rabbit, edge by tiny edge, so slowly and with such concentrated precision the meal took two hours to consume. I planned for this ritual all day, yearned for it, carried it out with the utmost focus and care.

(Knapp, 2003, pp. 48–49)

If, as you read Knapp's description of her eating ritual, you were reminded of symptoms of obsessive-compulsive disorder (OCD, see Chapter 7), you're on to something. Some symptoms of anorexia overlap with certain symptoms of OCD: obsessions about symmetry, compulsions to order objects precisely, and hoarding. However, other symptoms of OCD, such as obsessions about contamination and checking and cleaning compulsions, do not overlap with those of anorexia (Halmi et al., 2003).

Two Types of Anorexia Nervosa: Restricting and Binge-Eating/Purging

People with anorexia become extremely thin and maintain their very low weight in either of two ways: through restricting what they eat or through binge eating and then purging. DSM-IV-TR categorizes two types of anorexia based on which pattern is present:

- **Restricting type.** Low weight is achieved and maintained through severe undereating; there is no binge eating or purging. This is the classic type of anorexia, and Knapp's description in Case 10.1 illustrates the pattern of eating that is common among people with the restricting type.
- **Binge-eating/purging type.** Some people with anorexia may engage in **binge eating**—eating much more food at one time than most people would eat in the same context, for example, a “snack” might consist of a pint or two of ice cream with a whole jar of hot fudge sauce. Among people with anorexia, binge eating is followed by **purging**, which is an attempt to reduce the ingested calories by vomiting or by using diuretics, laxatives, or enemas.

Medical, Psychological, and Social Effects of Anorexia Nervosa

Anorexia has serious negative effects on many aspects of bodily functioning. Because of the daily deficit between calories needed for normal functioning and calories taken in, the body tries to make do with less. However, this process comes at a high cost.

Anorexia's Medical Effects

One possible effect of anorexia is that the heart muscle becomes thinner as the body, searching for an energy source to meet the its caloric demands, cannibalizes muscle generally, and the heart muscle in particular. *Muscle wasting* is the term used when the body breaks down muscle in order to obtain needed calories. When people with anorexia exercise, they are not building muscle but *losing* it, especially heart muscle—which can be fatal. Excessive exercise is actively discouraged in people with anorexia, and even modest exercise may be discouraged, depending on the person's weight and medical status.

A physical examination and lab tests are likely to reveal other medical effects of anorexia, which arise through the body's adjustments to conserve energy. These include low heart rate and blood pressure, abdominal bloating or discomfort, constipation, loss of bone density (leading to osteoporosis and easily fractured bones), and a slower metabolism (which leads to lower body temperature, difficulty tolerating cold temperatures, and downy hairs forming on the body to provide insulation). More visible effects include dry and yellow-orange skin, brittle nails, and loss of hair on the scalp. Symptoms that

Binge eating

Eating much more food at one time than most people would eat in the same context.

Purging

Attempting to reduce calories that have already been consumed by vomiting or using diuretics, laxatives, or enemas.

Underweight people may develop lanugo hair—fine downy hair similar to that of newborns—on the abdomen, back, and face. Lanugo disappears when normal weight is attained.

may not be as obvious to others include irritability, fatigue, and headaches (Mehler, 2003; Pomeroy, 2004). People, particularly females, with anorexia may also appear hyperactive or restless, which is probably a by-product of starvation, given that such behavior also occurs in starved animals (Klein & Walsh, 2005).

People with anorexia who purge may believe that they are getting rid of all the calories they've eaten, but they're wrong. In a starved state, the body so desperately needs calories that once food is in the mouth, the digestive process begins more rapidly than normal and calories may begin to be absorbed before the food reaches the stomach; even if vomiting occurs, some calories are still absorbed, although water the body needs is lost. Diuretics only decrease water in the body, not body fat or muscle, and laxatives and enemas simply get rid of water and the body's waste before it would otherwise be eliminated.

All four methods of purging—vomiting, diuretics, laxatives, and enemas—can result in dehydration, because they all deprive the body of needed fluids. And dehydration can create an imbalance in the body's *electrolytes*—salts that are critical for neural transmission and muscle contractions, including that of the heart muscle. When dehydration remains untreated, it can lead to death.

Psychological and Social Effects of Starvation

Researchers in the 1940s documented a number of unexpected psychological and social effects of extreme caloric restriction in what is sometimes called the *starvation study* (Keys et al., 1950). When healthy young men were given half their usual caloric intake for 6 months, they lost 25% of their original weight and suffered other changes: They became more sensitive to the sensations of light, cold, and noise; they slept less; they lost their sex drive; and their mood worsened. The men lost their sense of humor, argued with one another, and showed symptoms of depression and anxiety. They also became obsessed with food—talking and dreaming about food, collecting and sharing recipes. They began to hoard food and random items such as old books and knick-knacks. These striking effects persisted for months after the men returned to their normal diets. Such findings have since been substantiated by other researchers (Crisp et al., 1980). It is sobering that, even on this diet, the participants in the starvation study still ate more each day than do many people with anorexia.

The participants in the starvation study were psychologically healthy adult men, and they developed the noticeable symptoms after less than 6 months of caloric intake that would now be considered a relatively strict diet. Most people (females) with anorexia develop the disorder when they are younger than were the men in the study—and the consequences of restricting eating at a young age may be more severe than those noted in the starvation study. In fact, recent studies of the long-term consequences of starvation during puberty indicate an increased risk of heart disease (Sparén et al., 2004). Moreover, patients with anorexia generally maintain unhealthy eating patterns for much longer than the 6-month study period. The long-term effects of starvation can also lead people with anorexia to forget what it was like to live *without* the medical and psychological effects of the disorder. Marya Hornbacher described this kind of mental state:

I was beginning to harbor [the] delusion . . . that I was superhuman. When you coast without eating for a significant amount of time, and you are still alive, you begin to scoff at those fools who believe they must eat to live. It seems blatantly obvious to you that this is not true. You get up in the morning, you do your work, you run, you do not eat, you live.

You begin to forget what it means to live. You forget things. You forget that you used to feel all right. You forget what it means to feel all right because you feel like shit all of the time, and you can't remember what it was like before. People take the feeling of *full* for granted. They take for granted the feeling of steadiness, of hands that do not shake, heads that do not ache, throats not raw with bile and small rips from fingernails forced in haste to the gag spot.

(1998, pp. 110–111)

U. of MN School of Public Health CVD History Archive

In the starvation study Keys et al., (1950), men ate half their usual daily calories for 6 months. In this short amount of time, participants became preoccupied with food, as frequently occurs among people with anorexia. They also developed symptoms of depression and anxiety, which are often comorbid with anorexia. This photo shows a researcher obtaining information about a participant's physiology before the participant begins to restrict his caloric intake.

Some people with anorexia may have such distorted thinking about their weight and body that they may come to believe that there's really nothing wrong with their weight or restricted food intake (Csipke & Horne, 2007; Gavin, Rodham, & Poyer, 2008). A minority may come to view anorexia as a lifestyle choice rather than a disorder. Unfortunately, anorexia has serious physical and mental health consequences, which are swept under the rug by such attempts to reframe the condition.

Problems With the DSM-IV-TR Definition of Anorexia Nervosa

Criticisms of the DSM-IV-TR definition of anorexia focus on the specific criteria and the classification of the two types: restricting and binge-eating/purging. In this section we first consider problems with the diagnostic criteria and then examine problems with the classification into the two types of anorexia.

Problems With the Diagnostic Criteria

Researchers and clinicians point to significant problems with three of the four DSM-IV-TR criteria for anorexia nervosa:

- *Refusal to maintain a healthy body weight* (Criterion A). Research suggests that this criterion may be of little value in predicting an individual's medical status, prognosis, or outcome (Garfinkel, Kennedy, & Kaplan, 1995). The extent to which someone is underweight does not accurately predict the degree or type of medical problems she will develop or how she will fare over time. Moreover, the body weight cutoff point of "85% of that expected" doesn't take into account the range of healthy weights in the population, changes in growth due to puberty, or cultural factors that can lead a person's weight to vary (Franko et al., 2004; Herzog & Delinsky, 2001).
- *Fear of becoming fat or of gaining weight* (Criterion B). Such fear may not characterize people with anorexia in non-Western cultures such as that of Hong Kong. Rather, a fear of gaining weight appears to be a by-product of a Western cultural value of thinness (Keel & Klump, 2003; Lee, Ho, & Hsu, 1993; Walsh & Kahn, 1997). Some researchers and clinicians propose that this criterion should instead highlight the overemphasis on the importance of controlling eating rather than focus on weight (Palmer, 2003). Further research can clarify whether people who are preoccupied with controlling eating (rather than being afraid of gaining weight) and meet the other three DSM-IV-TR criteria for anorexia are different in any other way from people who meet all four of the DSM-IV-TR criteria.
- *Amenorrhea* (Criterion D). Many researchers suggest that this diagnostic criterion should be deleted because it is not reliably associated with the degree of weight loss or the outcome of the eating disorder. Some women continue to menstruate at low weights; other women develop amenorrhea before losing a significant amount of weight (Cachelin & Maher, 1998; Garfinkel et al., 1996). Moreover, among females diagnosed with anorexia, those who have amenorrhea are similar to menstruating females with anorexia in terms of body image problems, depression, personality disorders, and the severity of the eating disorder (Garfinkel et al., 1996).

Problems With the Types

The goal of delineating types or subtypes of a disorder is to identify and organize useful information, such as distinguishing the prognosis or course of one type from another. The two types of anorexia in DSM-IV-TR do not achieve this goal. Patients diagnosed with one type often shift to the other type over time (Eddy et al., 2008). For example, at an 8-year follow-up, one study found that 62% of those with the restricting type had changed to the binge-eating/purging type; in fact, only 12% of those who had been restrictors never developed any binge/purge symptoms. These findings suggest that the restricting type may be an earlier phase of the disorder for some patients (Eddy et al., 2002).

Key Concepts and Facts About Anorexia Nervosa

- The hallmark of anorexia nervosa is a refusal to maintain a healthy weight; DSM-IV-TR defines the weight cutoff as less than 85% of expected body weight. Other criteria include an intense fear of becoming fat or gaining weight, distortions in body image, and amenorrhea. DSM-IV-TR includes two types of anorexia: restricting and binge-eating/purging.
- Anorexia can lead to significant medical problems, most importantly muscle wasting (particularly of heart muscle), as well as low heart rate, low blood pressure, loss of bone density, and decreased metabolism. Other symptoms include irritability, headaches, fatigue, and restlessness. All methods of purging—vomiting, diuretics, laxatives, and enemas—can cause dehydration because they primarily eliminate water, not calories, from the body.
- Starvation also leads to various psychological and social problems, including a heightened sensitivity to light, cold, and noise, poor sleep and mood, irritability, anxiety, and preoccupation with food.

- Critics of the DSM-IV-TR diagnostic criteria for anorexia point out that the criteria of low weight and amenorrhea aren't highly associated with general medical status, prognosis, or outcome. Also, the two types of anorexia—restricting and binge-eating/purging—may better represent stages of the disorder rather than distinct paths it can take.

Making a Diagnosis

- Reread Case 10.1 about Caroline Knapp, and determine whether or not her eating-related symptoms meet all of the criteria for anorexia nervosa. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision? If you decide that her symptoms do meet the criteria, which DSM-IV-TR type of anorexia is the most appropriate and why?

Bulimia Nervosa

Marya Hornbacher describes her descent into bulimia nervosa:

I woke up one morning with a body that seemed to fill the room. Long since having decided I was fat, it was a complete crisis when my body, like all girls' bodies, acquired a significantly greater number of actual fat cells than it had ever possessed. At puberty, what had been a nagging, underlying discomfort with my body became a full-blown, constant obsession. . . . When I returned [from the bathroom after throwing up], everything was different. Everything was calm, and I felt very clean. Everything was in order. Everything was as it should be. . . .

I remember devouring piece after piece [of a loaf of bread, toasted with butter], my raging, insatiable hunger, the absolute absence of fullness. I remember cheerfully heading off for my bath. Night, I said. Locking the bathroom door, turning the water on, leaning over the toilet, throwing up in a heave of delight. . . . But the delight did not last long. The daily bingeing was making me heavier. . . . Though the purging was initially rare—maybe once or twice a week—it was right about this time that I began to get in trouble at school. With frequency. I got into fights. My grades fluctuated, notes were sent home about my disruptive behavior.

(1998, pp. 40–44).

For Hornbacher, as for many people with bulimia, the maladaptive eating behaviors started off as an attempt to cope with negative feelings about weight, appearance, or eating “too much.” As in her case, such behaviors can become entrenched and lead to additional negative feelings; the maladaptive eating behaviors and ensuing feelings can create their own problems. In this section we examine the criteria for bulimia nervosa, and the medical effects of the disorder; we then discuss criticisms of the diagnostic criteria and consider the disproportionately high prevalence of the related disorder, *eating disorder not otherwise specified*.

What Is Bulimia Nervosa?

A key feature of *bulimia nervosa* (often simply referred to as *bulimia*) is repeated episodes of binge eating followed by inappropriate efforts to prevent weight gain. Such inappropriate efforts to prevent weight gain are categorized by DSM-IV-TR as either purging or nonpurging:

- The *purging type* includes vomiting or using diuretics, laxatives, or enemas.
- The *nonpurging type* involves other behaviors to prevent weight gain, such as fasting or excessive exercise. Exercise is considered excessive by mental health clinicians if the individual feels high levels of guilt when she postpones or misses a workout (Mond et al., 2006).

As noted in the section on anorexia, a person with anorexia may purge or fast. In those cases, according to DSM-IV-TR, the symptoms that distinguish anorexia from bulimia are the low weight and related amenorrhea. Because women with bulimia nervosa are in the normal weight range—or possibly overweight—they generally continue to menstruate. Bulimia is twice as prevalent as anorexia (American Psychiatric Association, 2000) and, like anorexia, is much more prevalent among females (Keel et al., 2006). The DSM-IV-TR criteria for bulimia nervosa are presented in Table 10.3, and additional facts about the disorder are listed in Table 10.4.

Table 10.3 ▶ DSM-IV-TR Diagnostic Criteria for Bulimia Nervosa

- A.** Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
- (1) eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
 - (2) a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
- B.** Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.
- C.** The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.
- D.** Self-evaluation is unduly influenced by body shape and weight.
- E.** The disturbance does not occur exclusively during episodes of Anorexia Nervosa.

Table 10.4 ▶ Bulimia Nervosa Facts at a Glance

Prevalence

- Over the course of a lifetime, 1–2% of women and 0.1–0.5% of men are likely to develop the disorder (Hoek & van Hoeken, 2003; Hudson et al., 2007).

Comorbidity

- Up to 75% of people with bulimia have at least one other disorder, often an anxiety disorder (Godart et al., 2003; Hinrichsen et al., 2003; Kaye et al., 2004; Keck et al., 1990; Milos et al., 2002; Schwalberg et al., 1992) or depression (American Psychiatric Association, 2000).
- About 30% of those with bulimia will also develop substance abuse or dependence at some point during their lifetime, which may evolve from initial use of stimulants for weight loss (American Psychiatric Association, 2000).

Onset

- Bulimia usually begins in late adolescence or early adulthood (American Psychiatric Association, 2000). It may develop in older adults, however (Beck et al., 1996).
- Those in more recent birth cohorts (that is, those born more recently) have a higher risk for developing bulimia (Hudson et al., 2007).

Course

- At a 15-month follow-up, almost a third of those diagnosed with bulimia still met the criteria for the diagnosis; at a 5-year follow-up, that proportion dropped to 15% (Fairburn et al., 2000). However, people who no longer meet the DSM-IV-TR criteria for the disorder may nevertheless continue to have persistent symptoms of bulimia, although not the number, frequency, or intensity specified by the criteria (Ben-Tovim, 2003; Keel & Mitchell, 1997; Keel et al., 1999; Wade et al., 2006).
- People who have less intense negative attitudes about their bodies and who function better in daily life are more likely to have a healthier outcome (Ben-Tovim, 2003; Collings & King, 1994; Keel et al., 1999).
- People with bulimia who also have or have had a substance use disorder generally do not fare as well as those without this comorbid disorder (Keel et al., 1999).

Gender Differences

- Approximately 75–90% of those with bulimia nervosa are female (Hoek & van Hoeken, 2003; Hudson et al., 2007).

Cultural Differences

- Some studies find significant differences in prevalence, frequency, and symptoms of eating disorders across ethnic groups within the United States. Specifically, black and Hispanic American women are less likely to be diagnosed with bulimia than are Asian American or white American women (Alegria et al., 2007; Nicdao et al., 2007; Striegel-Moore et al., 2003; Taylor et al., 2007). Other studies find fewer meaningful differences in symptoms and prevalence rates across ethnic groups (see Arriaza & Mann, 2001; Franko et al., 2007; Walcott, Pratt, & Patel, 2003).

Often, people with bulimia don't simply eat normally at meals and then binge between meals (Walsh, 1993). Rather, they try to control what they eat, restricting their caloric intake at meals (trying to be "good" and eat less), but later become ravenous and their hunger feels out of control. They then binge eat, which in turn makes them feel physically and emotionally "bad" because they "lost control" of themselves. As a result of such feelings, they may purge and subsequently strive to eat less, restricting their caloric intake at meals and creating a vicious cycle of restricting, bingeing, and usually purging. As one woman notes: "I don't eat all day and then I come home from work and binge. I always tell myself I'm going to eat a normal dinner, but it usually turns into a binge" (Fitzgibbon & Stolley, 2000). In Case 10.2, Gabriella tells a similar story.

CASE 10.2 ► FROM THE OUTSIDE: Bulimia Nervosa

[Gabriella is] a young Mexican woman whose parents moved to the U.S. when she was just a child. While her mother and father continue to speak Spanish at home and place a high value on maintaining their Mexican traditions, Gabriella wants nothing more than to fit in with her friends at school. She chooses to speak only English, looks to mainstream fashion magazines to guide her clothing and make-up choices, and wants desperately to have a fashion-model figure. In an attempt to lose weight, Gabriella has made a vow to herself to eat only one meal a day—dinner—but on her return home from school, she is rarely able to endure her hunger until dinnertime. She often loses control and ends up "eating whatever I can get my hands on." Frantic to keep her problem hidden from her family, she races to the store to replace all the food she has eaten.

(Fitzgibbon & Stolley, 2000)

Dr. Craig Mabrito

Frequent vomiting can permanently erode dental enamel, shown here, and lead to cavities and related problems.

Medical Effects of Bulimia Nervosa

Like anorexia, bulimia can lead to significant physical changes and medical problems. For instance, chronic vomiting, a purging method used by Marya Hornbacher, can cause the parotid and salivary glands (in the jaw area) to swell (creating a kind of "chipmunk" look) and can erode dental enamel, making teeth more vulnerable to cavities and other problems. Those who use syrup of ipecac (which is toxic) to induce vomiting may develop heart and muscle problems (Pomeroy, 2004; Silber, 2004).

Furthermore, many people with bulimia use laxatives regularly, which can lead to a permanent loss of intestinal functioning as the body comes to depend on the chemical laxatives to digest food and eliminate waste. In such cases, the malfunctioning intestinal section must be surgically removed (Pomeroy, 2004). Bulimia can also produce constipation, abdominal bloating and discomfort, fatigue, and irregular menstruation (Pomeroy, 2004). As noted earlier in the section on anorexia, all forms of purging can cause dehydration and an imbalance of the body's electrolytes, which disrupt normal neural transmission and heart conductance. Case 10.3 illustrates how the medical effects of bulimia can create significant—and enduring—problems.

CASE 10.3 ► FROM THE INSIDE: Bulimia Nervosa

A 32-year-old woman describes how bulimia nervosa has affected her:

My life revolves around food and exercise. Because of my abuse of diet pills and purging, I had a stroke when I was 23. I now have headaches. I am at risk of having another stroke, and this time I have a high chance of not coming out of it. Emotionally, it's a daily battle. I'm depressed because I want to eat, and I'm depressed because I know if I do eat, I'll get fat and gain all the weight back that I have lost.

Everyone around me is terrified that I may die from this, and it has put a lot of stress on my marriage. I have no bedroom life anymore because I refuse to let my husband touch me or even look at my body. My kids are affected greatly by it because I usually have no energy to do anything with them, and when I do have energy, I am staying busy to burn the calories I have put in my body.

(Anonymous, 2003, p. 382)

Problems With the DSM-IV-TR Diagnostic Criteria

Like that of anorexia, the DSM-IV-TR diagnosis of bulimia has received criticism. Specific criticisms focus on the definition of the term *binge eating*, the two types of bulimia that DSM-IV-TR specifies, and the issue of whether bulimia is sufficiently distinct from anorexia. Let's examine these criticisms.

Problems Defining Binge Eating

DSM-IV-TR's definition of binge eating (see Criterion A in Table 10.3) is subjective: Who determines whether the amount of food is larger than most people would eat, the patient or the therapist? In fact, research has found that calories consumed during "binge episodes" vary widely from episode to episode and person to person (Rossiter & Agras, 1990); thus, what some consider to be a binge, others might view as an unexceptional meal.

In addition, the elements of the DSM-IV-TR criteria that focus on the timing of binge eating (episodes occur within a 2-hour period and twice weekly for at least 3 months) are not based on research results and don't predict the course of the disorder or its prognosis (Franko et al., 2004; Garfinkel et al., 1995; Kendler et al., 1991). To see the implications of this criticism, let's compare two women, Tess, whose symptoms meet the timing criteria, and Jen, whose symptoms do not. Tess binges three times a week for 4 months and has enough of the other symptoms to be diagnosed with bulimia. Jen binges and purges once a week, usually in a 3-hour stint; however, twice every semester, during midterms and finals weeks, she binges and purges almost every day. She's been doing it since she was a freshman in high school, 7 years ago. Her bingeing and purging do not meet the timing criteria, and thus she would not be diagnosed with bulimia; however, her bingeing and purging cannot be considered "normal."

Problems With the Types of Bulimia

The classification of purging versus nonpurging types of bulimia doesn't appear to be useful: Comparisons of people who have the two types have not been able to document meaningful differences between the two groups, other than the specific compensatory behaviors used to prevent weight gain (Gleaves, Lowe, Green, et al., 2000; Gleaves, Lowe, Snow, et al., 2000; Williamson et al., 2002). That is, the two groups are similar in terms of the disorder's onset, course, outcome, and other variables. In fact, research has found that whether or not someone with bulimia is impulsive is the characteristic that best predicts course and prognosis, not whether her diagnosis is the purging or nonpurging type (Favaro et al., 2005). Examples of behaviors that indicate impulsivity include stealing, running away, and seeking out dangerous situations, as well as abusing substances (Fischer, Smith, & Anderson, 2003; Wonderlich & Mitchell, 2001).

Is Bulimia Distinct From Anorexia?

About half of people with anorexia go on to develop bulimia (Bulik et al., 1997; Tozzi et al., 2005), which may indicate that anorexia and bulimia are not distinct but rather represent phases of the same eating disorder, with the symptoms shifting over time. A person's diagnosis may better reflect where she is in the course of

the eating disorder at the time she is diagnosed. Similarly, the types of each eating disorder—restricting and binge-eating/purging types for anorexia and purging and nonpurging types for bulimia—may represent different paths of the same underlying eating disorder. Consistent with this view, the two eating disorders and their types, as outlined in DSM-IV-TR, do not provide unique information about the course or prognosis of the disorder (Eddy et al., 2007; Franko et al., 2004).

In fact, the characteristics of the binge-eating/purging type of anorexia have more in common with those of bulimia than with those of the restricting type of anorexia (Gleaves, Lowe, Green, et al., 2000; Herzog et al., 1999). All that distinguishes the binge-eating/purging type of anorexia from bulimia is the low weight and consequent amenorrhea. In contrast, the restricting type of anorexia involves both a very different approach to eating (or not eating) and different coping styles, such as extreme self-regulation.

Eating Disorder Not Otherwise Specified

Many people with significantly disturbed eating don't meet all the criteria for anorexia or bulimia; those individuals are diagnosed with **eating disorder not otherwise specified (EDNOS)**. Studies have found that as many patients are diagnosed with EDNOS, 4–6% of the general population of Americans (Herzog & Delinsky, 2001), as with anorexia and bulimia combined (Andersen, Bowers, & Watson, 2001; Fairburn & Bohn, 2005; Fairburn & Walsh, 2002; Ricca et al., 2001).

DSM-IV-TR defines EDNOS as follows: “The mental disorder appears to fall within the larger category [of eating disorders] but does not meet the criteria of any specific disorder within that category” (American Psychiatric Association, 2000). The definition of EDNOS does not specify particular criteria, and so people who are given this diagnosis have a wide range in the number and duration of symptoms. Nevertheless, people diagnosed with EDNOS often fall into one of three groups. One group consists of people with **partial cases**, meaning that their symptoms meet some of the diagnostic criteria for a specific disorder but not enough to justify the diagnosis of that disorder. An example of a partial case of anorexia would be a woman whose symptoms meet all the other criteria for the disorder but who is not amenorrheic; she would thus be diagnosed with EDNOS.

Another group consists of people with **subthreshold cases**; they have symptoms that fit all the diagnostic criteria for a specific disorder, but at levels lower than required for the diagnosis of that disorder. Jen, described earlier, has a subthreshold case of bulimia because she usually binges only once a week, which is less frequently than twice weekly as specified by the DSM-IV-TR criterion (Fairburn & Walsh, 2002); Jen would therefore be diagnosed with EDNOS if her symptoms impaired her functioning or caused her significant distress.

A third group consists of people who have a variant of an eating disorder that has received significant attention: **binge-eating disorder**, which is characterized by frequent episodes of rapid uncontrolled eating of large quantities of food, even when not hungry, without subsequent purging (American Psychiatric Association, 2000). Typically, those with binge-eating disorder feel distressed by their binge eating; people with this eating pattern are usually overweight (Grucza, Przybeck, & Cloninger, 2007; Hudson et al., 2007). Binge-eating disorder is *not* listed as an “official” eating disorder in DSM-IV-TR. Rather, it is a provisional diagnosis; ongoing research will help determine whether it should be included as a distinct disorder in DSM-V and, if so, what the specific diagnostic criteria should be. Research to date suggest that the prevalence of binge-eating disorder is more similar for males and females than is found for other eating disorders, and that this disorder is more common than anorexia nervosa and bulimia nervosa combined (Grucza, Przybeck, & Cloninger, 2007; Hudson et al., 2007).

Most people with EDNOS have attitudes and behaviors regarding weight, food, and body image that are similar to those of people with anorexia and bulimia. The only significant difference is that people with EDNOS don't meet the specific

Eating disorder not otherwise specified (EDNOS)

The diagnosis given when an individual's symptoms of disordered eating cause significant distress or impair functioning but do not meet the full criteria for a diagnosis of anorexia nervosa or bulimia nervosa.

Partial cases

The designation given to cases in which patients have symptoms that meet only some of the necessary criteria, but not enough symptoms to meet all the criteria for the diagnosis of a disorder.

Subthreshold cases

The designation given to cases in which patients have symptoms that fit all the necessary criteria, but at levels lower than required for the diagnosis of a disorder.

Binge-eating disorder

A provisional diagnosis of the variant of an eating disorder characterized by frequent episodes of rapid uncontrolled eating of large quantities of food, even when not hungry, without subsequent purging; according to DSM-IV-TR, patients with binge-eating disorder receive a diagnosis of EDNOS.

DSM-IV-TR criteria for either of those other eating disorders (Fairburn, Palmer et al., in preparation; Turner & Bryant-Waugh, 2004). Some people diagnosed with EDNOS may have had anorexia or bulimia but then improved to the point where their symptoms no longer meet the criteria for either disorder. These people still have clinically significant symptoms of an eating disorder, however. This was true of Marya Hornbacher: As her eating disorder symptoms abated, she no longer met the criteria for either anorexia or bulimia, and her diagnosis was changed to EDNOS.

Based on research findings, an alternative system for categorizing anorexia and bulimia would require three fundamental changes (Gleaves, Lowe, Green, et al., 2000):

1. Eliminate the purging and nonpurging types of bulimia because they do not meaningfully distinguish course or outcome.
2. Create a separate diagnosis for bingeing and purging (both bulimia and binge-eating/purging type of anorexia) as distinct from a restricting type of anorexia. Moreover, this new diagnosis of bulimia (bingeing and purging, regardless of weight) may be better conceptualized on a continuum (Lowe et al., 1996), without a rigid cutoff of duration and frequency of symptoms; such a reformulation would reduce the number of EDNOS diagnoses.
3. Within the binge-eating/purging type, put those with anorexia and normal-weight bulimia on the same continuum, but at different points with regard to weight.

Key Concepts and Facts About Bulimia Nervosa

- Bulimia nervosa is characterized by recurrent episodes of binge eating followed by inappropriate efforts to prevent weight gain.
- DSM-IV-TR specifies two types of bulimia: the purging type (which is characterized by vomiting or the use of diuretics, laxatives, or enemas) and the nonpurging type (which involves fasting or excessive exercise).
- Bulimia is twice as prevalent as anorexia, and much more common among women than men.
- All purging methods can cause dehydration, which leads to electrolyte imbalances and possibly death. Chronic vomiting can lead to enlarged parotid and salivary glands and can erode dental enamel. Chronic laxative use can lead to permanent loss of intestinal functioning.
- Aspects of the DSM-IV-TR criteria for a diagnosis of bulimia have been criticized: The definition of “binge eating” is subjective,

the purging/nonpurging distinction does not correlate meaningfully with course or prognosis, and bulimia and anorexia do not appear to be distinct disorders but rather may be different phases of the same disorder.

- Problems with the criteria for anorexia and bulimia are apparent in the prevalence of eating disorder not otherwise specified (EDNOS), which is greater than anorexia and bulimia combined. One subset of patients with EDNOS have binge-eating disorder.

Making a Diagnosis

- Reread Case 10.2 about Gabriella, and determine whether or not her symptoms meet the criteria for bulimia nervosa. Specifically, list which criteria apply and which do not. If you would like more information to determine her diagnosis, what information—specifically—would you want, and in what ways would the information influence your decision?

Understanding Eating Disorders

Why do eating disorders arise? Marya Hornbacher asked this question and ventured the following response:

While depression may play a role in eating disorders, either as cause or effect, it cannot always be pinpointed directly, and therefore you never know quite what you’re dealing with. Are you trying to treat depression as a cause, as the thing that has screwed up your life and altered your behaviors, or as an effect? Or simply *depressing*? Will drug therapy help, or is that a Band-Aid cure? How big a role do your upbringing and family play? Does the culture have anything to do with it? Is your personality just

problematic by nature, or is there, in fact, a faulty chemical pathway in your brain? If so, was it there before you started starving yourself, or did the starving put it there? . . . All of the above?

(1998, pp. 195–196)

In this passage, Hornbacher is trying to understand how, or why, some people—but not others—develop an eating disorder. Note that she mentions explanations that involve all three of the types of factors in the neuropsychosocial approach, although she does not consider ways in which such factors might interact. Given that up to half of the people with one of the eating disorders (anorexia, bulimia, or EDNOS) have had or will have another of these disorders, it makes sense to examine the etiology of these disorders collectively, rather than individually.

People with an eating disorder generally do not come to the attention of researchers until after they've developed the disorder. Yet once the eating disorder has developed, it is difficult to disentangle causal factors from factors that reflect the altered eating habits and poor nutrition that predated the full-blown disorder. In other words, it is challenging for researchers to distinguish the *causes* of eating disorders from the widespread *effects* of eating disorders on neurological (and, more generally, biological), psychological, and social functioning.

This difficulty in untangling cause and effect means that researchers do not know which of the neuropsychosocial factors that are associated with eating disorders actually give rise to the disorders. All that can be said at this time is that a number of factors are associated with the emergence and maintenance of eating disorders (Dolan-Sewall & Insel, 2005; Jacobi et al., 2004; Streigel-Moore & Cachelin, 2001).

An additional challenge to researchers is the high rate of comorbidity of other psychological and medical disorders with eating disorders, which makes it difficult to determine the degree to which risk factors uniquely lead to eating disorders, rather than being associated more generally with the comorbid disorders (Jacobi et al., 2004; Johnson, Cohen, Kasen et al., 2002).

Neurological Factors: Setting the Stage

We've already noted that the excessive caloric restriction in anorexia leads to specific medical effects, notably changes in hormones, metabolism, and body functioning. The eating changes and purging involved in bulimia (and anorexia, if purging occurs) bring their own medical effects and biological changes. Researchers try to determine whether neurological (or other biological) abnormalities they find among people with an eating disorder might have caused the disorder, might be caused by the disorder, or are simply correlated with the disorder (Franko et al., 2004; Jacobi et al., 2004).

Brain Systems

Neuroimaging studies have revealed many differences between the brains of people with eating disorders and those of control participants (Frank et al., 2004; Kaye, Frank, et al., 2005; Takano et al., 2001). Most notably, people who have anorexia have unusually low activity in several key areas of the brain: (1) the frontal lobes, which are involved in inhibiting responses and in regulating behavior more generally (a deficit in such processing may contribute to eating too much or eating too little); (2) the portions of the temporal lobes that include the amygdala, which is involved in fear and other strong emotions (fear helps prevent people from putting themselves in danger, and dampening this emotion may contribute to eating disorders); (3) the parietal lobes, which may play a key role in representing body size; and (4) the anterior (i.e., front) part of the cingulate cortex, which lies in the frontal lobes at the midline of the brain and is involved in monitoring for conflicts among competing responses or among competing information retrieved from memory (Kuhl et al., 2008); a deficit here may contribute to problems in learning to inhibit dysfunctional behavior.

Examining groups of patients can be useful, insofar as general patterns of brain differences can help to identify key characteristics associated with a disorder. However,

if data from different groups (such as people with the restricting type of anorexia and people with the binge-eating/purging type) are averaged together, characteristics that are unique to one of the groups will not be detected. Thus, some research has focused specifically on particular groups, such as patients with the restricting type of anorexia. In one study, for example (Kojima et al., 2005), researchers examined the effects of weight gain in this one group. They found that some parts of the brain, in particular, the parietal lobes, became more active after these patients gained weight. The parietal lobes represent spatial properties, including size, and may be involved in representing the body image, which includes information about how large a person feels herself to be. However, other parts of the brain, such as the basal ganglia and the cerebellum, became less active after the patients gained weight—and the decreases in activation in both brain areas were larger for the patients who gained more weight. Both the basal ganglia and the cerebellum may be critical in controlling repetitive behaviors, such as those that underlie recurrent bingeing. The lower activation in these areas may indicate that the patients were less actively controlling their eating after gaining weight. However, even after gaining weight, the patients in this study still had less activity in the anterior cingulate cortex than did the control participants. As noted earlier, this brain area is involved in monitoring for conflicts either in actual responses or stored information. These patients may not be able to monitor accurately conflicts between different responses (such as eating versus not eating) or among stored information (such as about appearance versus health)—and this problem persists even after they have gained weight.

Neuroimaging studies not only have documented many abnormalities in the functioning of different parts of the brain in people who have eating disorders, but also have shown that the structure of the brain itself changes with these disorders. In fact, anorexia is associated with loss of both gray matter (cell bodies of neurons) and white matter (myelinated axons of the neurons) in the brain (see Chapter 2; Addolorato et al., 1997; Frank et al., 2004; Herholz, 1996). The gray matter carries out various sorts of cognitive and emotion-related processes (such as those involved in learning and in fear responses). Deficits in white matter may imply that different parts of the brain are not communicating appropriately, which could contribute to the problems patients with anorexia have when they try to convert an intellectual understanding of their disorder into changes in their behavior. Many of these structural deficits improve when the patient recovers, although they do not necessarily disappear completely (Frank et al., 2004; Herholz, 1996). Thus, an eating disorder may have long-term consequences for a person's cognitive abilities and emotional responses.

Neural Communication: Serotonin

Losing large amounts of weight (as occurs in anorexia) and the associated malnutrition clearly change the amounts of serotonin and other neurotransmitters. We will focus here on serotonin because it is involved in regulating a wide variety of behaviors and characteristics that are associated with eating disorders, including binge eating and irritability (Hollander & Rosen, 2000; McElroy et al., 2000).

Neuroimaging research has shown that serotonin receptors function abnormally in patients with anorexia and bulimia (Kaye, Bailer et al., 2005; Kaye, Frank, et al., 2005). However, such research does not show that either eating disorder causes these abnormalities; the abnormalities in the serotonin receptors could be produced by the eating disorder itself or, instead, could be related to specific symptoms or characteristics (such as the impulsivity that is associated with bulimia). Thus, it is important that evidence seems to imply that the serotonin receptors are abnormal before patients develop anorexia. As discussed in Chapters 6 and 7, serotonin is related to mood and anxiety. Prior to developing anorexia, patients tend to be anxious and obsessional, and these traits persist even after recovery, which suggests a biologically based anxious temperament; this temperament may be related to serotonin levels or functioning (Kaye et al., 2003). Consistent with this view, researchers have found that people with anorexia are less responsive to serotonin than normal (Kaye, Bailer, et al., 2005).

In addition, some researchers suggest that eating less actually reduces anxiety, in part, by reducing serotonin levels. This reduction may be a result of lower levels of tryptophan in the diet, which occurs when food intake is reduced; tryptophan is a building block of serotonin. When young rats are fed severely restricted diets, their serotonin activity is reduced (Huether et al., 1997). Thus, the effects of reduced eating can affect the functioning of the serotonin system.

Researchers have also found that people with bulimia are not as responsive to serotonin as is typical (Kaye et al., 2000; Smith, Fairburn, & Cowen, 1999). In fact, the worse the symptoms of bulimia, the less responsive to serotonin the patient generally is (Jimerson et al., 1992). As with anorexia, tryptophan levels are related to symptoms of bulimia (Smith, Fairburn, & Cowen, 1999), and, as noted above, reduced tryptophan levels have the effect of reducing serotonin activity, which in turn can reduce anxiety.

The precise mechanism that underlies the dysregulation of serotonin and the abnormal behaviors found in eating disorders remains unknown, as do the reasons for its differing manifestations in anorexia and bulimia.

Genetics

When Marya Hornbacher told her parents that she had been making herself throw up, her mother said, “I used to do that.” Did Hornbacher’s genes predispose her to developing bulimia? If so, to what degree would genes play a role? As is true for those with mood disorders and anxiety disorders, people with an eating disorder are more likely than average to have family members with an eating disorder, but not necessarily the same one (Lilenfeld & Kaye, 1998; Strober et al., 2000).

Like genetic studies of other types of disorders, such studies of eating disorders compare identical twins to fraternal twins (see Chapter 2). The research findings indicate that anorexia has a substantial heritability, but estimates range from as little as 33% to as much as 88% (Bulik, 2005; Jacobi et al., 2004), depending on how the study was carried out. Twin studies of bulimia also indicate that the disorder is influenced by genes, and also yield a wide range of estimates of heritability, from 28% to 83% (Bulik 2005; Jacobi et al., 2004). Given that many people with bulimia previously had anorexia, it isn’t surprising that both disorders have the same wide range of heritabilities—there is significant overlap in the two populations.

The large variation in heritabilities may simply indicate, once again, that genes aren’t destiny; the way the environment interacts with the genes is also important. However, studies have shown that the shared family environment (such as how many books are in the house or how many meals a family eats all together) may not be as influential as the nonshared, unique environment (such as different relationships between each child and her father, the extent to which an individual is teased about weight, or unique peer group experiences) (Agliata, Tantleff-Dunn, & renk, 2007; Bulik, 2004; Klump et al., 2002). We’ll examine such nonshared environmental factors in more detail in the next two sections.

Psychological Factors: Thoughts of and Feelings About Food

Eating and breathing are both essential to life, but eating provides more than sustenance. It can evoke powerful feelings, memories, and thoughts. Hornbacher recalls her associations to eating:

My memories of childhood are almost all related to food. . . . I was my father’s darling, and the way he showed love was through food. I would give away my lunch at school, then hop in my father’s car, and we’d drive to a fast-food place and, essentially, binge.

My mother was another story altogether. She ate, some. She would pick at cottage cheese, nibble at cucumbers, scarf down See’s Candies. But she, like my father, and like me, associated food with love, and love with need.

(1998, p. 27)

And once an eating disorder develops, the thoughts and behaviors associated with it can take on a life of their own, as Hornbacher reveals:

I stood in the kitchen after school, scarfing down food without tasting it, staring at the television without seeing it. I would go through the perfunctory motions: washing my dishes, going into the bathroom, puking. In the bedroom, I'd stare at the mirror. When I entered junior high, at twelve, I'd been throwing up almost daily for three years. In the seventh grade, it increased to two or three times a day. I began to do it whenever I got the chance.

(1998, p. 59)

Many risk factors are not uniquely associated with eating disorders. Factors such as gender (female), ethnicity (White), negative self-evaluation, sexual abuse and other adverse experiences, the presence of comorbid disorders (e.g., depression and anxiety disorders; Jacobi et al., 2004), and using avoidant strategies to cope with problems (Pallister & Waller, 2008; Spoor et al., 2007) are also associated with psychological disorders more generally. Thus, many researchers have focused on factors that are specifically related to symptoms of eating disorders: factors associated with food, weight, appearance, and eating. In the following sections we examine research findings about these factors.

Thinking About Weight, Appearance, and Food

Based on what you've already read about eating disorders, it shouldn't come as a surprise to learn that people with eating disorders have irrational and illogical thoughts about weight, appearance, and food. Specifically, these automatic and irrational thoughts tend to be about their own weight and appearance and their moral evaluation of eating (Garfinkel et al., 1992; Striegel-Moore, 1993). We consider these two kinds of thoughts in the following sections.

Excessive Concern With Weight and Appearance

Some people with eating disorders have excessive concern with and tend to overvalue their weight, body shape, and eating (Fairburn, 1997; Fairburn, Cooper, & Cooper, 1986). For instance, they may weigh themselves multiple times a day and get depressed when the scale indicates that they've gained half a pound. The two characteristics that are among the most consistent predictors of the onset of an eating disorder are dieting and being dissatisfied with one's body (Thompson & Smolak, 2001). Some people are so concerned with weight and appearance that their food intake, weight, and body shape come to define their self-worth. Such concerns help maintain bulimia in that people believe that their compensatory behaviors reduce their overall caloric intake (Fairburn et al., 2003).

Abstinence Violation Effect

Many people who have an eating disorder engage in automatic, illogical, black-or-white thinking about food: Vegetables are "good," whereas desserts are "bad." They may come to view themselves in the same way: They are "good" when acting to lose weight, "bad" when eating a "bad" food or when they feel that their eating is out of control. Once they are "bad" in a given situation, they might allow themselves to continue to be "bad." Because they have violated their rules for abstaining from "bad" eating behavior, they then proceed to ignore the rules and binge. This pattern illustrates the **abstinence violation effect** (Polivy & Herman, 1993), in which the violation of a self-imposed rule about food restriction leads to feeling out of control with food, which then leads to overeating. For instance, having taken a taste of a friend's ice cream, an individual thinks, "I shouldn't have had any ice cream; I've blown it for the day, so I might as well have my own ice cream—in fact, I'll get a pint and eat the whole thing." Then, after she eats the ice cream, she tries to negate the calories ingested during the binge by purging or using some other compensatory behavior. Thus, the abstinence violation effect explains bingeing that occurs after the individual has "transgressed."

Abstinence violation effect

The condition that arises when the violation of a self-imposed rule about food restriction leads to feeling out of control with food, which then leads to overeating.

Operant Conditioning: Reinforcing Disordered Eating

As with many disorders, operant conditioning plays a role in the development and maintenance of symptoms—in this case, symptoms of disordered eating. Let's examine how.

First, the symptoms of eating disorders—*anorexia*, *bulimia*, or *EDNOS*—may inadvertently be reinforced through operant conditioning. As Hornbacher recounts:

Eating disorders provide a little private drama. . . . And they are distracting. You don't have to think about any of the nasty minutiae of the real world, you don't get caught up in that awful boring thing called regular life, with its bills and its break-ups and its dishes and laundry and groceries and arguments over whose turn it is to change the litter box and bedtimes and bad sex and all that, because you are having a *real* drama, not a sitcom but a GRAND EPIC, all by yourself, and why would you bother with those foolish mortals when you could spend hours and hours with the mirror, when you are having the *most interesting* sado-masochistic affair with your own image?

(1998, p. 281)

Hornbacher points out that the symptoms of eating disorders, such as preoccupations with food and weight or bingeing and purging, can provide distractions from work pressures, family conflicts, or social problems. The never-ending preoccupations with food, weight, and body are negatively reinforced (remember that negative reinforcement is still *reinforcement*, but it occurs when something aversive is removed, which is not the same as punishment) because they can provide relief from what the person might otherwise be thinking about—ongoing concerns about relationships, finances, or feeling social isolated.

Second, operant conditioning occurs when restricting behaviors are positively reinforced by the person's sense of power and mastery over her appetite, although such feelings of mastery are often short-lived as the disease takes over (Garner, 1997). Hornbacher noted: "The anorexic body seems to say: I do not need. It says: Power over the self" (1998, p. 85). A third way in which operant conditioning affects eating disorders occurs when people are positively reinforced for "losing control" of their appetite and bingeing. How can losing control be positively reinforcing? Easy: They've set up the rules so that they get to eat certain foods they enjoy (positive reinforcement) only when they let themselves lose control of their food intake. That is, during a binge, people eat foods that they normally don't eat at all or eat only in small quantities—typically fats, sweets, or carbohydrates. This means that the only way some people can eat foods they may enjoy—such as ice cream, cake, candy, or fried foods—is by being "out of control."

Fourth, like preoccupations with food, weight, and body, the act of bingeing itself turns off unpleasant thoughts or feelings—and so bingeing is negatively reinforced because the binge provides a respite from these thoughts or feelings. Fifth, bingeing can also induce an endorphin rush, which creates a pleasant feeling much like a "runner's high," which is positively reinforcing. Sixth, operant conditioning may occur because purging can be negatively reinforcing by relieving the anxiety and fullness that are created by overeating.

Finally, operant conditioning can contribute to symptoms of eating disorders because of the social isolation that can arise from the symptoms: Bingeing and purging are more often done alone, and people with restricting anorexia often prefer to eat alone. To the extent that social interactions are stressful to people with eating disorders, the isolation can be a relief, and thereby reinforcing.

Personality Traits as Risk Factors

Particular personality traits are associated with—and are considered risk factors for—eating disorders: perfectionism, harm avoidance, neuroticism, and low self-esteem. *Perfectionism* is a persistent striving to attain perfection and excessive

self-criticism about mistakes (Antony & Swinson, 1998; Franco-Paredes et al., 2005). Numerous studies find perfectionism to be higher in people with eating disorders than in people who do not have these disorders (Forbush, Heatherton, & Keel, 2007). High scores on measures of perfectionism persist after people recover, which suggests that this personality trait may exist before an eating disorder arises and may increase the risk for developing such a disorder (Franco-Paredes et al., 2005); high perfectionism may lead to an intense drive to attain a desired weight or body shape, and thus contribute to the thoughts and behaviors that underlie an eating disorder. As illustrated in Figure 10.2, perfectionists are painfully aware of their imperfections, which is aversive for them. This heightened awareness of personal flaws—real or imagined—is called *aversive self-awareness* and leads to significant emotional distress, which may temporarily be dulled by focusing on immediate aspects of the environment, such as occurs with bingeing. Thus, bingeing may provide an escape from the emotional distress associated with perfectionism (Blackburn et al., 2006; Heatherton & Baumeister, 1991).

Figure 10.2

10.2 ▸ Bingeing as Escape For perfectionists, bingeing can be an escape from aversive feelings. Being aware of imperfections (referred to as *aversive self-awareness*) causes emotional distress. People high in perfectionism try to decrease the ensuing emotional distress by focusing on immediate aspects of the environment (referred to as *cognitive narrowing*), which they attain through bingeing (Blackburn et al., 2006; Heatherton & Baumeister, 1991).

People with eating disorders, more than other people, also tend to exhibit *harm avoidance*—the characteristic of trying to avoid potentially harmful situations or stimuli (Cassin & von Ranson, 2005). For instance, they are likely to be organized planners rather than carefree and spontaneous, which minimizes their exposure to potential danger. When people high in harm avoidance are preoccupied with stimuli related to food, weight, or appearance (perhaps because of a social factor such as a familial focus on such matters), they may be too concerned with their caloric intake and be more likely to perceive threats or dangers—such as eating “too much”—that other people don’t see.

Another aspect of personality associated with eating disorders is *neuroticism* (see Chapter 2), which is characterized by a propensity toward anxiety and emotional reactivity (Eggert, Levendosky, & Klump, 2007; Miller et al., 2006). One Spanish study tracked females aged 12–21 who did not have an eating disorder. Those who had high levels of neuroticism were more likely to develop an eating disorder 18 months later (Cervera et al., 2003). People high in neuroticism may be more sensitive to criticism in general, and when this trait is combined with other risk factors (such as an overvaluation of weight and appearance), they may take to heart criticisms or comments related to their weight and appearance more than other people do (Davis, Claridge, & Fox, 2000).

Finally, people who have low self-esteem may try to raise their self-esteem by controlling their food intake, weight, and shape, believing that such changes will increase their self-worth (Geller et al., 2000; Striegel-Moore, Silberstein, & Rodin, 1986). For instance, they may think, “If I restrict my calories, that’ll prove that I’m in control of myself and worthy of respect.” However, efforts to increase self-worth in this way end up having a paradoxical effect: To the extent that attempts

to control food intake, weight, and shape fail, self-esteem falls even lower; these people feel they've failed, yet again, to achieve something they wanted.

Dieting, Restrained Eating, and Disinhibited Eating

Frequently restricting the intake of specific foods—such as “fattening” foods—or overall caloric intake (as when dieting or trying to maintain one's current weight) is referred to as **restrained eating**. If you've ever been on some type of diet, you know that continuing to adhere to such restrictions can be challenging. And at times the diet may feel so constraining that you get discouraged and frustrated, and simply give up—which can lead to a bout of *disinhibited eating*, bingeing on a restricted type of food or simply eating more of a nonrestricted type of food (Polivy & Herman, 1985). In fact, it is common for dieters, and people with eating disorders, to alternate restrictive eating with disinhibited eating (Fairburn et al., 2005; Polivy & Herman, 1993, 2002).

In addition to dieting, researchers have identified other stimuli that may trigger disinhibited eating. One stimulus is eating more calories than intended or desired, which can trigger the abstinence violation effect. Seemingly paradoxically, disinhibited eating can also be triggered by an upcoming diet. This phenomenon is known as the *last supper effect* (Eldredge, Agras, & Arnow, 1994) and is sometimes referred to as “diet tomorrow, feast today” because it leads people to increase their food intake before starting a diet.

To study the last supper effect, researchers examined whether anticipation of a week-long diet would lead a group of restrained

eaters (those with a significant history of failed attempts at dieting) to consume more than a group of restrained eaters not anticipating a diet (Urbszat, Herman, & Polivy, 2002). Volunteers (some of whom were restrained eaters, and some of whom were not) were assigned either to a group that would be on a low-fat diet for a week or to a group that would have no change in food intake. The participants were then asked to eat cookies from a plate and rate their taste; after they'd made their ratings, participants were allowed to finish the cookies on the plate if they wanted. As shown in Figure

Figure 10.3

10.3 ► The Last Supper Effect

Restrained eaters who were about to diet ate more than did restrained eaters who were not about to diet. Unrestrained eaters ate comparable amounts, regardless of whether those participants were about to diet.

Source: Adapted from Urbszat, Herman, & Polivy, 2000.

10.3, results were consistent with the last supper effect: Restrained eaters who were anticipating the low-fat diet ate more cookies than did either their restrained counterparts not anticipating the diet or unrestrained eaters in either condition.

Restrained eaters can also become insensitive to internal cues of hunger and fullness. In order to maintain restricted eating, they may stop eating before they get a normal feeling of fullness and so end up trying to tune out sensations of hunger. If they binge, they may eat past the point of normal fullness. They therefore need to rely on external guides, such as portion size or elapsed time since their last meal, to control their food intake (Polivy & Herman, 1993). However, using external guides to direct food intake requires cognitive effort—to monitor the clock or to calculate how much food was last eaten and how much food should be eaten next—and when a person is thinking about other tasks (such as a job or homework assignment), he or she may temporarily stop using external guides and simply eat, which in turn may lead to disinhibited or binge eating (Baumeister et al., 1998; Kahan, Polivy, & Herman, 2003). In fact, the results of one study showed that restrained eaters ate more when they were asked to inhibit their emotional responses to a video clip (which required them to increase their cognitive effort) than when they did not inhibit their emotional responses (Vohs & Heatherton, 2000).

Restrained eating

Restricting intake of specific foods or overall number of calories.

Other Psychological Disorders as Risk Factors

Another factor associated with the subsequent development of an eating disorder is the presence of a psychological disorder in early adolescence (see Figure 10.4), particularly depression. A longitudinal study of 726 adolescents found that having a depressive disorder during early adolescence was associated with a higher risk for later dietary restriction, purging, recurrent weight fluctuations, and the emergence of an eating disorder. This was the case even when researchers statistically controlled for other disorders or eating problems before adulthood (Johnson, Cohen, Kotler, et al., 2002).

Social Factors: The Body in Context

Various social factors contribute to eating disorders. One social factor is the role played by family and friends, who have the potential to minimize or amplify an individual's attention to food, weight, and body, and who can help shape individual's thoughts, feelings, and behaviors related to food, weight, and body. Another social factor is culture, which can contribute to eating disorders by promoting an ideal body shape; the media, in turn, propagate the cultural ideal. In this section we discuss these social factors as well as explanations of why so many more females than males develop eating disorders.

The Role of Family and Peers

As mentioned earlier, eating disorders tend to run in families. However, researchers have not found it easy to disentangle the influences of genes from those of the family itself for two main reasons:

1. Family members provide a model for eating, body image, and appearance concerns through their own behaviors (Stein, Woolley, Cooper, et al., 2006). For example, parents who spend a lot of time on their appearance before leaving the house model that behavior for their children.
2. Family members affect a child's concerns through their responses toward the child's body shape, weight, and food intake (Stein, Woolley, Senior, et al., 2006; Tantleff-Dunn, Gokee-LaRose, & Peterson, 2004; Thompson et al., 1999). For example, if a parent inquires daily about how much food his or her child ate at lunch or weighs the child daily, the child learns to pay close attention to caloric intake and daily fluctuations in weight.

Children whose parents are overly concerned about these matters are more likely to develop an eating disorder (Strober, 1995). Marya Hornbacher described her parents' eating styles:

While my relationship to my parents has always been very complex, there is also the simple fact that both of them used food—one to excess, one to absence—as a means of communication, or comfort, or quest. Food was a problem in my family. A big problem. . . . My father was a periodic heavy drinker, ate constantly, and was forever obsessing about his weight—he would diet, berate himself for falling off his diet, call himself a pig. My mother was a former—or was it closet?—bulimic with strange eating habits. She'd eat normally for a while, then go on a diet, pick at her food, push it away, stare at her butt in the mirror.

(1998, pp. 22–23)

Hornbacher was a keen observer of her parents' behaviors, especially those related to food, weight, and appearance. And she realized that she modeled her own behavior on theirs.

Figure 10.4

10.4 ▶ Psychiatric Disorders and the Risk of Developing an Eating Disorder

The more psychological disorders an adolescent—particularly a female adolescent—has, the more likely he or she is to develop an eating disorder (Johnson, Cohen, Kasen, & Brook, 2002).

Children often pay attention to and imitate how their family members behave; when parents are concerned about food, weight, and appearance, they may intentionally or inadvertently pass on these concerns to their children.

M Nader/Getty Images

For a teenage girl, her friends' comments can have a lasting influence on how she feels about her body, her willingness to diet, and her self-esteem.

Parents and siblings aren't the only ones who can shape a person's relationship to eating, food, and body. Friends also play a role, especially if they tease or criticize an individual concerning her weight, appearance, or food intake; such comments can have a lasting influence on her (dis)satisfaction with her body, her willingness to diet, and her self-esteem. Such influences can make a person more vulnerable to developing an eating disorder (Cash, 1995; Crowther et al., 2002; Fabian & Thompson, 1989; Keery et al., 2005; Muir, Wertheim, & Paxton, 1999; Tantleff-Dunn, Gokee-LaRose, & Peterson, 2004).

Unfortunately, many girls and women feel that symptoms of eating disorders—particularly preoccupations with food and weight—are “normal” and that talking about these topics is a way to bond with others. Hornbacher was aware of this social facet of eating disorders and its underlying drawback:

Women use their obsession with weight and food as a point of connection with one another, a commonality even between strangers. Instead of talking about *why* we use food and weight control as a means of handling emotional stress, we talk ad nauseum about the fact that we don't like our bodies.

(1998, p. 283)

The Role of Culture

Many people believe that eating disorders have become more common and pervasive in recent decades. Hornbacher associated the increased prevalence with a cultural fad:

Starving is the feminine thing to do these days, the way swooning was in Victorian times. In the 1920s, women smoked with long cigarette holders and flashed their toothpick legs. In the 1950s, women blushed and said tee-hee. In the 1960s, women swayed, eyes closed, with a silly smile on their faces. My generation and the last one feign disinterest in food. We are “too busy” to eat, “too stressed” to eat.

(1998, p. 118)

Is Hornbacher right—are eating disorders a cultural phenomenon of modern times, as swooning was in the Victorian era? Yes and no. A meta-analysis of the incidence of eating disorders across cultures over the 20th century found only a small increase in the number of cases of anorexia. This finding indicates that Hornbacher was wrong to think that self-induced starvation—anorexia—is a type of “fad” in mental illness (Keel & Klump, 2003). Historically however, people who engaged in self-starvation were not obsessed about their weight; this weight concern has only been observed recently, suggesting that its inclusion in the DSM-IV-TR definition of anorexia may be related to a transient cultural fad.

However, Hornbacher seems to have been on the right track about the “fad” aspect of bulimia. In contrast to the stable incidence of anorexia over time, the incidence of bulimia significantly increased from 1970 to 1990 (Keel & Klump, 2003)—suggesting a cultural influence (Striegel-Moore & Cachelin, 2001)—and bulimia only arises in the context of concerns about weight.

Three elements come together to create the engine driving the culturally induced increase in eating disorders (Becker et al., 2002):

1. a cultural ideal of thinness,
2. repeated media exposure to this thinness ideal, and
3. an individual's assimilation of the thinness ideal.

In order to examine the cultural ideal of thinness, David Garner and colleagues (1980) undertook an innovative study: They tracked the measurements of Miss America contestants and *Playboy* centerfold playmates over time and found that their waists and hips gradually became smaller. Other studies have found similar results (Andersen & DiDomenico, 1992; Field et al., 1999; Nemeroff et al., 1994). In fact, while the size of playmates' bodies has decreased over time (as assessed

by the body mass index, or BMI, an adjusted ratio of weight to height), the average BMI of women age 20–29 has increased (see Figure 10.5). During the same period studied by Garner and colleagues, the prevalence of eating disorders increased in the United States. It is not clear whether the contestants and playmates were creating or following a cultural trend in ideal body shape. What is clear is that society's pressure to be thin increases women's—and girls'—dissatisfaction with their bodies, which is a risk factor for eating disorders (Grabe & Hyde, 2006; Lynch et al., 2008; Stice et al., 2003).

The cultural influence on weight and appearance isn't limited to women: Men who regularly engage in activities such as modeling and wrestling, which draw attention to their appearance and weight, are increasingly likely to develop eating disorders (Brownell & Rodin, 1992; Garner, Rosen, & Barry, 1998; Sundgot-Borgen, 1999). Similarly, men who have a heightened awareness of appearance (Ousley, Cordero, & White, 2008), such as some in the gay community, are also more likely to develop an eating disorder (Carlat, Camargo, & Herzog, 1997; Russell & Keel, 2002).

Eating Disorders Across Cultures

Eating disorders occur throughout the world, but are found mainly in industrialized Western or Westernized countries (Kuboki et al., 1996; Lee, Chiu, & Chen, 1989; Lee, Hsu, & Wing, 1992; Pike & Walsh, 1996). Immigration to a Western country and internalization of Western norms increase the risk of developing symptoms of an eating disorder, as occurs among those immigrating from China and Egypt to Western countries (Bilukha & Utermohlen, 2002; Lee & Lee, 1996; Perez et al., 2002; Stark-Wroblewski, Yanico, & Lupe, 2005). Westernization (or modernization) of a culture similarly increases dieting (Gunewardene, Huon, & Zheng, 2001; Lee & Lee, 2000), which is a risk factor for eating disorders. In addition, as girls and women move into a higher socioeconomic bracket, they are more likely to develop an eating disorder (Lee & Lee, 2000; Polivy & Herman, 2002; Soomro et al., 1995).

Within the United States, prevalence rates of eating disorders vary across ethnic groups, based on different ideals of beauty and femininity: Native Americans have a higher risk for eating disorders than do other ethnic groups (Crago, Shisslak, & Estes, 1996) and black Americans have had the lowest risk (Andersen & Hay, 1985; Crago, Shisslak, & Estes, 1996; Mulholland & Mintz, 2001; Striegel-Moore et al., 2003). However, prevalence rates are increasing among black and Latina women (Franko et al., 2007; Gentile et al., 2007; Perez & Joiner, 2003; Shaw et al., 2004; Taylor et al., 2007), perhaps because of the growing number of ethnic models in mainstream ads who are as thin as their white counterparts (Brodey, 2005).

Finally, prevalence rates of eating disorders across ethnic groups may vary for people at different ages; studies with participants from younger cohorts find fewer differences across ethnic groups (Wade, 2007).

The Power of the Media

The power of the media to influence cultural ideals of beauty and femininity is illustrated by the results of an innovative study in Fiji by Anne Becker and colleagues (2002). Prior to 1995, there was no television in Fiji, a group of islands in the South Pacific. Traditional Fijian culture promoted robust body shapes and appetites, and there were no cultural pressures for thinness or dieting. Researchers collected data from adolescent girls shortly after the introduction of television in 1995 and again 3 years later. At the beginning of the study, when a large body size was the cultural

Figure 10.5

10.5 ► Women's Body Size Over Time: Playmates and Average Young Women

Over the last four decades, the size (specifically, the body mass index, BMI) of the average young woman's body has become heavier (orange line); over the same period of time, the body size of *Playboy* playmates has become thinner (purple line), presenting an increasingly unattainable ideal.

Jeff Greenberg/Photo Edit

When females move from a non-Western country to a Western country, their risk of developing an eating disorder increases.

ideal, they found almost no one who felt they were “too big or fat.” After 3 years of watching television (primarily shows from Western countries), however, 75% reported that they felt “too big or fat” at least some of the time. In addition, feeling too big was associated with dieting to lose weight, which had become very prevalent: 62% of the girls had dieted within the prior 4 weeks.

In this study in Fiji, over three quarters of the participants reported that television influenced their body image and that they wanted to change the shape of their body to resemble those of the Western television characters. To emulate the characters, they changed their hairstyles, clothes, and behavior and tried to reshape their bodies through dieting and, for some (11%), through purging. Consider one girl’s comments: “When I look at the characters on TV . . . and I just look at the body, the figure of that body, so I say, ‘look at them, they are thin and they all have this figure’, so I myself want to become like that, to become thin” (Becker et al., 2002, p. 513). Moreover, 30% of the participants viewed the characters on TV as role models for work and career issues. The researchers noted that this profound change occurred over the course of only 3 years, which is particularly dramatic given the long history of a fuller figure as the Fijian cultural ideal.

A similar process might be occurring in industrialized societies, where ideals of thinness saturate the environment through television, movies, magazines, advertisements, books, and even cartoons. A number of studies have documented associations between media exposure and disordered eating (Bissell & Zhou, 2004; Kim & Lennon, 2007; Stice et al., 1994); for instance, the more time adolescent girls spent watching television, the more likely they were to report disordered eating a year later (Harrison & Hefner, 2006). However, not all females who view these media images end up with an eating disorder. Some people are more affected than others, perhaps because of their combination of neurological, psychological, and social risk factors. For them, chronic exposure to these types of images may tip the scales and set them on a course toward an eating disorder (Levine & Harrison, 2004).

Objectification Theory: Explaining the Gender Difference

How, exactly, the cultural ideal of thinness makes women vulnerable to eating disorders is explained by **objectification theory**, which posits that girls learn to consider their bodies as objects and commodities (Fredrickson & Roberts, 1997). Western culture promotes the view of male bodies as agents—instruments that perform tasks—and of female bodies as objects mainly to be looked at and evaluated in terms of appearance (see Figure 10.6). Marya Hornbacher recounted her sense of being objectified:

I remember the body from the outside in. . . . There will be copious research on the habit of women with eating disorders perceiving themselves through other eyes, as if there were some Great Observer looking over their shoulder. Looking, in particular, at their bodies and finding, more and more often as they get older, countless flaws.

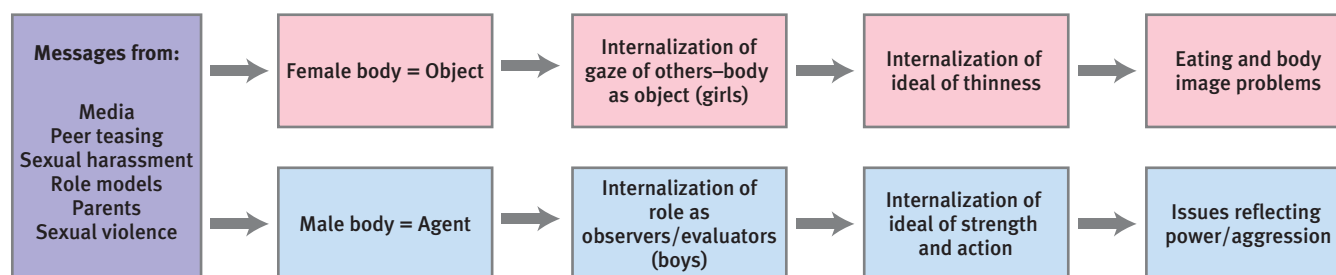

(1998, p. 14)

Implicit in Hornbacher’s musings about her perceptions of her body is the sense of her body as an object—to be looked at and evaluated and, all too frequently, found defective.

According to the theory, objectification encourages eating disorders because female bodies are evaluated according to the cultural ideal, and women strive to have their bodies conform so that they will be positively evaluated. As they internalize the ideal of thinness, they increase their risk for eating disorders (Calogero, Davis, & Thompson, 2005; Thompson & Stice, 2001)—especially in combination with learning to see their bodies as objects from the outside: As Hornbacher noted, if they hold an ideal of thinness and see their bodies as objects, they become more

Objectification theory

The theory that girls learn to consider their bodies as objects and commodities.

Figure 10.6

10.6 ▶ Objectification and Eating Problems Objectification theory helps to explain the large gender difference in the prevalence of eating disorders. This theory proposes that whereas boys are encouraged to view their bodies as instruments that can perform tasks (agents), girls are encouraged to consider their bodies as objects and commodities to be evaluated (objects)—which makes girls more vulnerable to developing an eating disorder.

Source: Adapted from Smolak & Murnen, 2004.

likely to pay attention to their flaws and to feel ashamed of their bodies, and these feelings motivate restrained eating (Fredrickson & Roberts, 1997; Moradi, Dirks, & Matteson, 2005; Smolak & Murnen, 2004).

Consider this study: Female participants alone in a dressing room with a full-length mirror were asked to try on either a one-piece swimsuit or a sweater. While wearing the new clothing, the women completed a checklist assessing body shame (questions included: “I wish I were invisible,” “I wish I could cover my body.”). They then took part in a “food taste test” (cookies). Women who tried on bathing suits reported more shame about their bodies and subsequently ate less than their sweater-clad counterparts. Male participants who wore bathing suits did not exhibit this response (Fredrickson et al., 1998).

The objectification process typically begins before adulthood. As girls enter puberty, when female bodies are increasingly viewed in sexual terms, comments on their bodies—such as catcalls or whistles when they walk down the street—may increase their sense of bodies as objects or commodities (Bryant-Waugh, 1993; Larkin, Rice, & Russell, 1999). Children learn these cultural messages early. Today, even preschool children attribute more negative qualities to fat women than to fat men (Turnbull, Heaslip, & McLeod, 2000).

Another explanation for the gender difference in prevalence rates of eating disorders focuses on the politics of a cultural ideal of thinness for women. Some researchers note that as women’s economic and political power has increased, female models have become thinner and less curvaceous, creating a physical ideal of womanhood that is harder—if not impossible—to meet. Women then spend significant time, energy, and money trying to emulate this thinner ideal through exercise, diet, medications, and even surgery, which in turn dissipates their economic and political power (Barber, 1998; Bordo, 1993).

Although today males are much less likely to develop any type of eating disorder than are women, this large gender discrepancy may not last. Data suggest that male physical ideals are increasingly unrealistic: Male film stars and Mr. Universe winners are increasingly muscular (Pope, Phillips, & Olivardia, 2000), paralleling the changes in women’s bodies in the media. Just as females covet bodies similar to those promoted in the media, so do males (Ricciardelli et al., 2006): Two-thirds of men want their bodies to be more similar to cultural ideals of the male body (McCabe & Ricciardelli, 2001a, 2001b; Ricciardelli &

Many female dolls have unattainable physical proportions; this is increasingly also becoming true of male dolls. As seen in this comparison of a 1960 G. I. Joe action figure (left) with one from 2000 (right), male action figures have become more muscular over the last 25 years (Baghurst et al., 2006).

McCabe, 2001). However, rather than suffer from the specific sets of symptoms for anorexia or bulimia, males are more likely to develop EDNOS, with symptoms that focus on muscle building, either through excessive exercise or steroid use (Weltzin et al., 2005). Sam, in Case 10.4, is preoccupied with losing muscle mass.

CASE 10.4 ► FROM THE INSIDE: EDNOS

Forty-year-old Sam recounts his preoccupations with his muscles:

I would get up in the morning and already wonder whether I lost muscle overnight while sleeping. I would rather be thinking about the day and who I was going to see, et cetera. But instead, the thoughts always centered on my body. Throughout the day, I would think about everything I ate, every physical movement I did, and whether it contributed to muscle loss in any way. I would go to bed and pray that I would wake up and think about something else the next day. It's a treadmill I can't get off of.

(Olivardia, 2007, pp. 125–126)

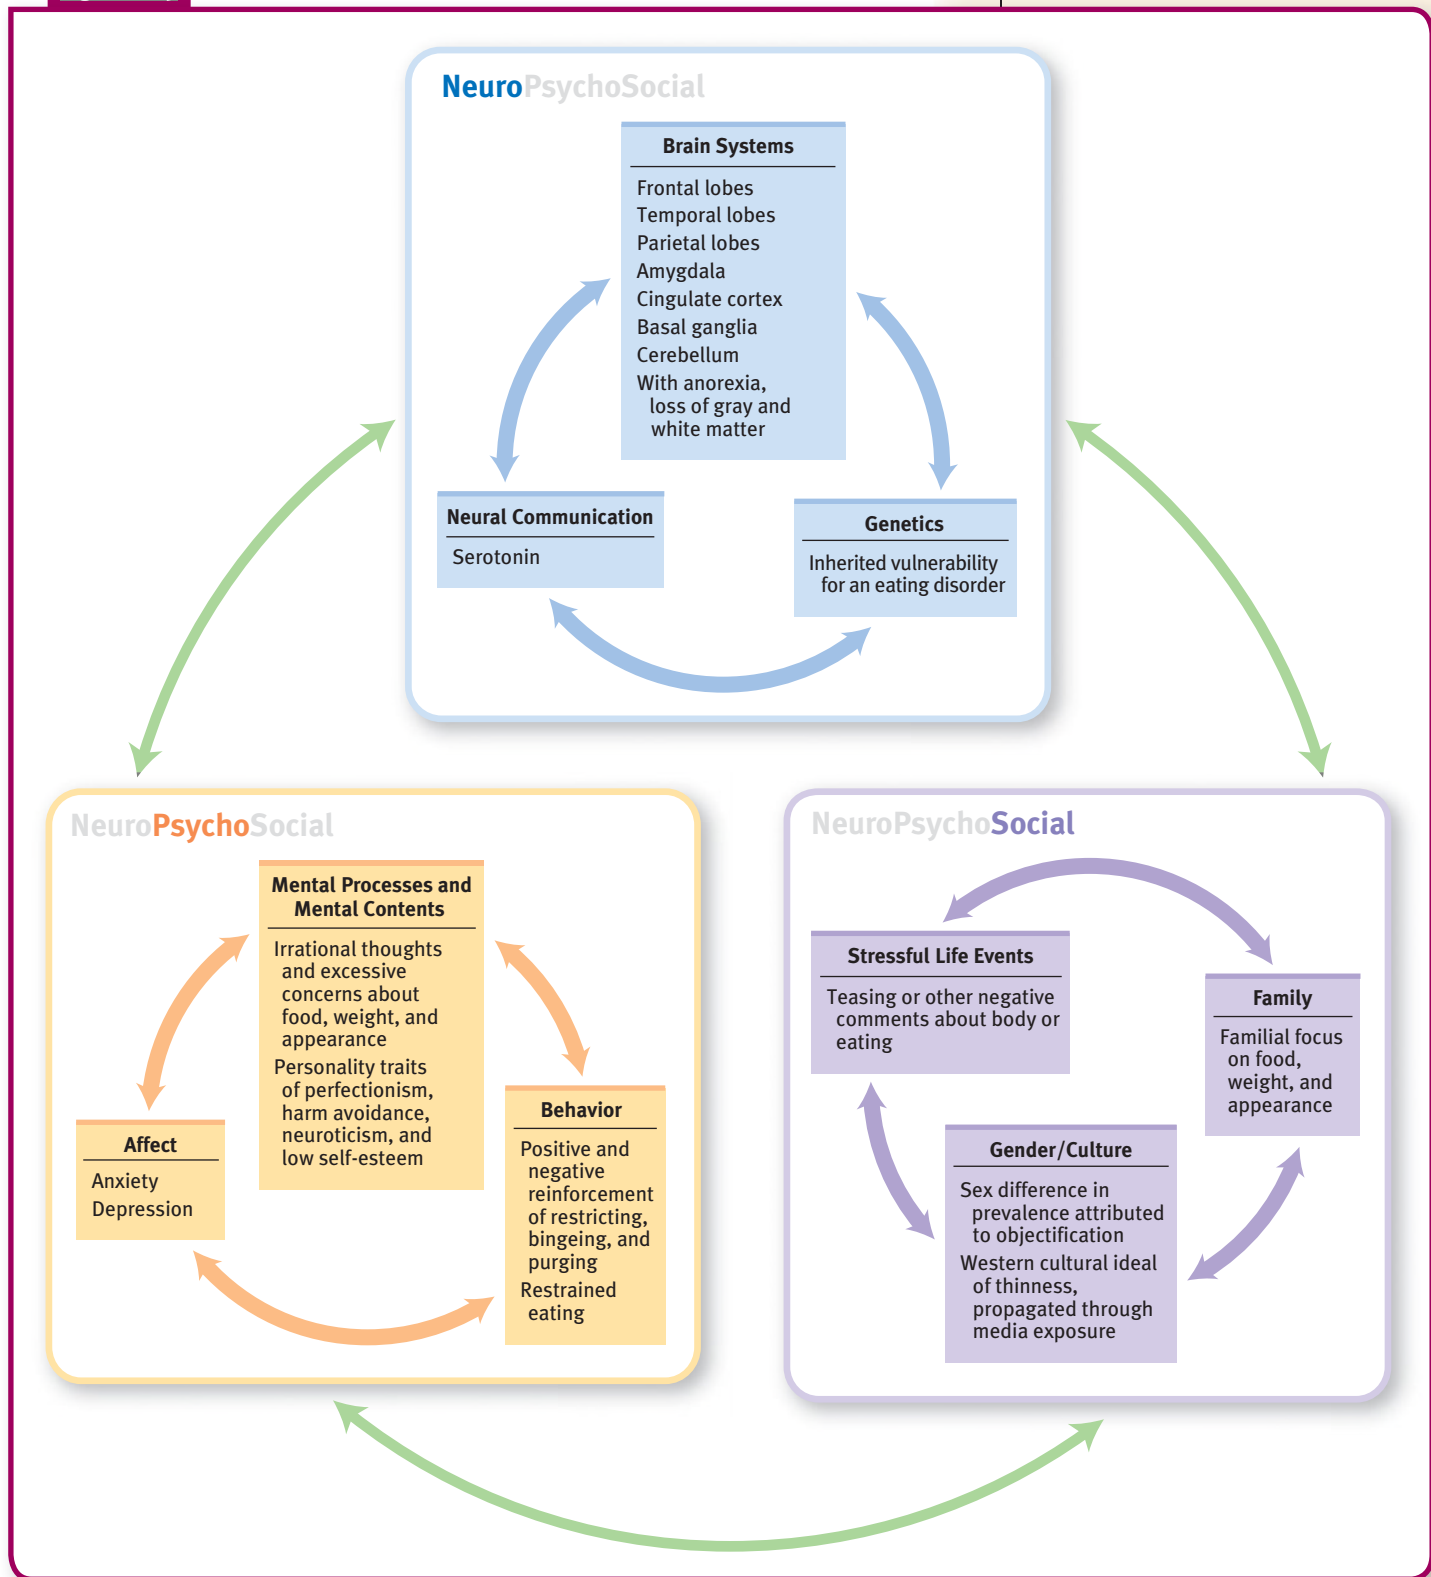

FEEDBACK LOOPS IN ACTION: Eating Disorders

As we have seen, many neurological, psychological, and social factors are associated with the development and maintenance of eating disorders. Let's look at some theories about how these factors interact through feedback loops.

Most females in Western societies are exposed to images of thin women as ideals in the media, yet only some women develop an eating disorder. Why? Neurological factors (such as a genetic vulnerability) may make some individuals more susceptible to the psychological and social factors related to eating disorders (Bulik, 2005). For instance, researchers hypothesize that young women who are prone to anxiety (neuroticism)—which is both a psychological factor and a neurological factor—are more susceptible to the effects of a familial focus on appearance, a social factor (Davis et al., 2004). In turn, these two factors are associated with weight preoccupation, creating feedback loops: After statistically controlling for body size, researchers found that young women who were preoccupied with weight were more prone to anxiety and were more likely to have families that focused on appearance. That is, two factors—anxiety proneness and familial focus on appearance—were most associated with the young women's preoccupation with weight. This preoccupation in turn leads to anxiety focused on weight and appearance.

A preoccupation with weight can also lead to dieting, which can create its own neurochemical changes (neurological factor) that may lead to eating disorders (Walsh et al., 1995). In addition, the stringent rules that people may set for a diet can lead them to feel out of control with eating if they “violate” those rules (psychological factor). Further, people with higher levels of perfectionism and body dissatisfaction (psychological factors) may seek out comments about their appearance (social factor) or pay more attention to appearance-related comments (psychological factor) (Halmi et al., 2000). Figure 10.7 illustrates the feedback loops for eating disorders.

Figure 10.7

Key Concepts and Facts About Understanding Eating Disorders

- It is particularly difficult for researchers to establish cause-and-effect relationships among the factors associated with eating disorders. This difficulty arises because the symptoms themselves—restricting, bingeing, purging, excessive exercise, malnourishment—create neurological (and other biological), psychological, and social changes.
- Neurological factors associated with eating disorders include:
 - unusually low activity in the frontal, temporal, and parietal lobes, as well as the anterior cingulate cortex, the basal ganglia, and the cerebellum. However, these neural patterns may vary for specific types of anorexia, and may be affected by dieting. Patients with anorexia also have reduced gray and white matter;
 - reduced responsiveness to serotonin, a neurotransmitter involved in mood, anxiety, and binge eating. One theory about the role of serotonin in bulimia involves tryptophan, a building block of serotonin;
 - a tendency for eating disorders tend to run in families, as well as evidence of substantial heritability, which indicates that genes play a role.
- Psychological factors related to eating disorders include:
 - irrational thoughts and excessive concerns about weight, appearance, and food;
 - binge eating as a result of the abstinence violation effect;
 - positive and negative reinforcement of symptoms of eating disorders (restricting, bingeing, and purging);
 - certain personality traits: perfectionism, harm avoidance, neuroticism, and low self-esteem;
 - disinhibited eating, triggered by the last supper effect, especially in restrained eaters; and
 - comorbid psychological disorders in female adolescents, particularly depression.
- Social factors related to eating disorders include:
 - family members and friends who provide a model for eating, concerns about weight, and focus on appearance through their own behaviors and responses to others;
 - cultural factors, which play a key role, as evidenced by the increased prevalence over time of bulimia and concern about weight that is part of anorexia. Specific cultural factors include a cultural ideal of thinness and repeated exposure—through the media—to this ideal, as well as the individual's assimilation of this ideal. People in Western and Westernized countries are more likely to develop eating disorders than are people from non-Western and developing countries;
 - conflicting gender roles in Western societies and a tendency to view women's bodies as objects and search for bodily flaws (objectification theory).

Treating Eating Disorders

One important goal when treating a patient with anorexia is to help the patient attain a medically safe weight through increased eating or decreased purging; if that safe weight cannot be reached with outpatient treatment, then inpatient treatment becomes imperative. Marya Hornbacher describes one aspect of her treatment for anorexia and how she felt about it:

Denied food, your body and brain will begin to obsess about it. It's the survival instinct, a constant reminder to eat, one that you try harder and harder to ignore, though you never can. Instead of eating, you simply *think* about food all the time. You dream about it, you stare at it, but you do not eat it. When you get to the hospital, you have to eat, and as truly terrifying as it is, it is also welcome. Food is the sun and the moon and the stars, the center of gravity, the love of your life. Being forced to eat is the most welcome punishment there is.

(1998, p. 151)

When someone with an eating disorder *isn't* underweight enough to require inpatient treatment, many different factors can be the initial targets of treatment. In this section we examine specific treatments that target neurological (and biological, more broadly), psychological, and social factors and the role of hospitalization.

Like treatment for other disorders, the intensity of treatment for eating disorders can range from hospitalization, day or evening programs, residential treatment, to outpatient treatment. In all these forms of treatment, cognitive-behavior therapy

(CBT) is generally considered the method of choice. Regardless of the severity of the eating disorder, frequent visits with an internist or family doctor are an important additional component of treatment. The physician determines whether a patient should be medically hospitalized and, if not, whether she is medically stable enough to partake in daily activities. Let's examine treatment options using the neuropsychosocial approach.

Targeting Neurological and Biological Factors: Nourishing the Body

Neurologically and biologically focused treatments are designed to create a pattern of normal healthy eating and to stabilize medical problems that arise from the eating disorder. Treatments that focus specifically on these goals include nutritional counseling to improve eating, medical hospitalization to address significant medical problems, and medication to diminish some symptoms of the eating disorder as well as symptoms of comorbid anxiety and depression.

A Focus on Nutrition

For people with any type of eating disorder, increasing the nutrition and variety of foods eaten—and not purged—is critical. A nutritionist will help develop meal plans for increasing caloric intake at a reasonable pace. In the process of nutritional counseling, the nutritionist may identify a patient's mistaken beliefs about food and weight; the nutritionist then seeks to educate the patient and thus help her correct such beliefs.

When very low weight patients with anorexia increase their food intake too aggressively, they can develop *refeeding syndrome*, in which rapidly shifting blood electrolyte levels can cause congestive heart failure, mental confusion, seizures, breathing difficulty, and possibly death (Mehler, 2001; Pomeroy, 2004; Swenne, 2000). For such low weight patients, caloric intake should increase at a moderate pace. Despite improved nutrition, menstruation may not restart (or begin) months after a woman's weight and body fat are in the normal range.

As people with anorexia begin to eat more, they may experience gastrointestinal discomfort. This may occur for two reasons: First, because of a lack of body fat, eating more may compress a section of the duodenum (a part of the intestine) that is on top of an important artery (Adson, Mitchell, & Trenkner, 1997). Second, when people eat no fat (or very small amounts of it), their ability to produce bile, which is necessary for the digestion of fats, diminishes. With reduced bile production, people may feel uncomfortable after eating fats. To minimize this discomfort, nutritionists suggest reintroducing fats slowly; bile production increases with increased fat consumption over the course of a couple of weeks.

Medical Hospitalization

The bodily effects of eating disorders—particularly anorexia—can be directly life-threatening. When medical problems related to eating disorders become severe, a *medical* hospitalization rather than a psychiatric hospitalization may be necessary. Medical hospitalization generally occurs in response to a medical crisis, such as a heart problem, gastrointestinal bleeding, or significant dehydration. The goal of medical hospitalization is to treat the specific medical problem and stabilize the patient's health.

Medication

Generally, various medications have not been found to help with the weight gain phase of treatment for anorexia (Crow et al., 2009; de Zwaan, Roerig, & Mitchell, 2004; Rivas-Vasquez, Rice, & Kalman, 2003; Walsh et al., 2006). However, once the patient's normal weight is restored, selective serotonin reuptake inhibitors (SSRIs) may help prevent the person from relapsing (developing anorexia again; Barbarich et al., 2004).

For bulimia, antidepressants—particularly SSRIs—may reduce some symptoms of the eating disorder. Compared to placebos, SSRIs can help decrease bingeing, vomiting, and weight and shape concerns, although other symptoms may still persist—including a fear of normal eating (Bacaltchuk, Hay, & Mari, 2000; Mitchell et al., 2001). Symptoms of comorbid depression may also be reduced by SSRIs. The SSRI prozac (*fluoxetine*) is the most widely studied medication for bulimia, and the FDA has approved it to treat this disorder. Studies of Prozac's effects on bulimia typically last no longer than 16 weeks, however, so it isn't clear how long the medication should be taken (de Zwaan, Roerig, & Mitchell, 2004). Moreover, as with other disorders, the beneficial effects of medication used to treat eating disorders typically stop soon after the medication is discontinued.

Targeting Psychological Factors: Cognitive-Behavior Therapy

Among the treatments that directly target psychological factors, CBT is the most extensively studied and is considered the treatment of choice (Pike, Devlin, & Loeb, 2004). CBT for eating disorders focuses primarily on changes in thoughts, feelings, and behaviors that are related to eating, food, and the body, at least in the initial stages. At the outset of treatment, the patient and therapist discuss who monitors the patient's weight and at what point inpatient treatment would be recommended and pursued (Pike, Devlin, & Loeb, 2004).

CBT for Anorexia

CBT for anorexia focuses on identifying and changing thoughts and behaviors that impede normal eating and that maintain the symptoms of the disorder. Cognitive restructuring can decrease the patient's irrational thoughts (such as the belief that starving means having self-control) and help the patient develop more realistic thoughts (for example, that appropriate eating indicates the ability to care for herself). The therapist also helps the patient to develop more adaptive coping strategies (Bowers & Ansher, 2008; Garner, Vitousek, & Pike, 1997; Wilson & Fairburn, 2007), such as expressing anger or disappointment directly to other people rather than hiding or denying such "negative" feelings. Treatment may also involve psychoeducation (about the disorder and its effects), training in self-monitoring (to notice hunger cues and become aware of problematic behaviors), and relaxation training (to decrease anxiety that arises with increased eating). Because low weight can affect cognitive functioning, irrational thoughts may not change substantially until the patient's weight increases (McIntosh et al., 2005). CBT can be effective in reducing symptoms of anorexia and has been shown to prevent relapses (Pike et al., 2003).

Because people with anorexia may not seek help voluntarily, motivation (or resistance) to change is often more of an issue than it is in the treatment of other disorders. Motivational enhancement therapy (see Chapter 9) may be employed to increase patients' willingness to change; with anorexia, this treatment might address the patient's goals that are unrelated to eating, food, and weight, and help her see how her behaviors—and the eating disorder symptoms—interfere with attaining those goals.

CBT for Bulimia

When used as a treatment for bulimia, CBT focuses on the thoughts, feelings, and behaviors that (1) prevent normal eating and (2) promote bingeing, purging, and other behaviors that are intended to offset the calories ingested during a binge. CBT also addresses thoughts, feelings, and behaviors that are related to body image and appearance and that maintain the symptoms of bulimia. In addition to focusing on symptoms of the disorder, CBT may address perfectionism, low self-esteem, and mood issues (Wilson & Fairburn, 2007). CBT for bulimia uses many

of the same methods as for anorexia: psychoeducation, cognitive restructuring, self-monitoring, and relaxation. In addition, treatment may employ a method used to treat obsessive-compulsive disorder (OCD): *exposure with response prevention* (discussed in Chapters 4 and 7). For bulimia, this method generally involves exposing the patient to anxiety-provoking stimuli, such as foods she would typically eat only during a binge. Patients are asked to consume a moderate amount of the binge food during a therapy session (the exposure), and the response prevention involves *not purging* or responding in another usual way to compensate for the calories ingested. The benefits of CBT for bulimia are well documented (Agras, Crow, et al., 2000; Fairburn et al., 1995; Ghaderi, 2006; Walsh et al., 1997).

Researchers have proposed three possible mechanisms to explain the beneficial effects of CBT as a treatment for bulimia (Wilson et al., 2002):

1. CBT leads to more normal eating.
2. CBT decreases patients' dietary restrictions, which reduces the risk of bingeing (and subsequent purging) because of hunger or inadequate nutrition.
3. CBT increases patients' ability to cope with potential *triggers* of bingeing and purging, which increases a sense of self-efficacy, which in turn further decreases bingeing and purging (Wilson & Fairburn, 2007).

Using CBT Manuals to Treat Eating Disorders

CBT manuals have been adapted for both anorexia and bulimia, although clinicians often need to deviate from the manuals (see Chapter 5 for a more general discussion about manual-based treatment). Such manuals provide a session-by-session guide with specific goals and techniques. As shown in Table 10.5, manual-based treatment may last 20 sessions or less, and generally consists of three phases, each of which has a different focus and uses different techniques. The first phase focuses on the behaviors themselves; the second focuses on the thoughts that underlie such behaviors; and the third focuses on how to prevent relapse. Research has shown that relapse is more likely to occur after treatment that uses behavioral techniques only and does not address the inappropriate thoughts about weight and appearance that underlie the problematic behaviors (Fairburn et al., 1993). Here's a therapeutic interchange from the second phase of treatment, addressing the underlying cognitive distortions that contribute to disordered eating behavior:

Therapist (T): Did you notice any situations leading to binge episodes or urges to binge in the past week that involve problem thoughts?

Patient (P) Well, I binged after skiing one day. I was upset, because I went skiing and the people were nicer to my friend than they were to me and I was sure that it was because she is thinner and prettier than I am.

T: I'm hearing some faulty reasoning here. Let's work to uncover the underlying problem thought.

Table 10.5 ▶ Three Phases of CBT for Bulimia

Phase of Treatment	Focus of Phase	Techniques Employed
Phase 1	Behavioral symptoms related to food and appearance	Psychoeducation; self-monitoring; assignments to normalize eating and decrease bingeing and purging, including exposure with response prevention
Phase 2	Cognitive symptoms related to the eating disorder	Cognitive restructuring of illogical thoughts pertaining to food, weight, appearance, purging, and self; problem solving
Phase 3	Relapse prevention	Problem solving about possible eating and appearance concerns or other factors likely to lead to relapse

Sources: Fairburn, Marcus, & Wilson, 1993; Pike, Devlin, & Loeb, 2004.

P: My friend is prettier than I am, so that means that people like her more and like me less, and she's thinner. So I guess the underlying problem thought is that people don't like me because I'm fat and ugly. [. . .]

T: What is the evidence to support the view that people don't like you because you are fat and ugly?

P: Well, I am fat and ugly.

T: I think you know that is subjective, not objective. [. . .]

P: More people talked to her than me.

(Agras & Apple, 1997, pp. 95–96; Agras & Apple, 2008, pp. 107–108)

Notice the underlying circularity in the patient's reasoning: Because the patient believes that more people talked to her friend than talked to her, that is "proof" that it was because her friend is thinner and prettier.

Efficacy of CBT for Treating Eating Disorders

Most people with eating disorders who improve significantly with CBT do so within the first month of treatment (Agras, Crow, et al., 2000). Others may improve somewhat but may stop treatment because they feel that it isn't helping them. Although CBT helps decrease their bingeing, purging, and dieting behaviors, up to 50% of patients retain some symptoms after the treatment ends (Lundgren, Danoff-Burg, & Anderson, 2004). One study of 48 patients who completely abstained from bingeing and purging after CBT found that 44% had relapsed 4 months later (Halmi et al., 2002). Those who relapsed had more eating rituals, were more preoccupied with food-related thoughts, and were less motivated to change their behavior.

Why does CBT not help everyone with an eating disorder? There's no simple answer. Some studies that examined the presence of comorbid disorders—particularly personality disorders—found that people with comorbid disorders tend to respond less well than those with only the eating disorder (Bandini et al., 2006; Bruce & Steiger, 2005). Although CBT may be the treatment of choice and helps many people with eating disorders, it clearly isn't a panacea.

Targeting Social Factors

Given the important role that social factors play in contributing to eating disorders, it is not surprising that various effective treatments directly target these factors. Treatments that target social factors include interpersonal therapy, family therapy, group-based inpatient treatment programs, and prevention programs.

Interpersonal Therapy

Interpersonal therapy (IPT) has been applied to eating disorders, in the form of manual-based treatment consisting of 4 to 6 months of weekly therapy (Fairburn, 1998). In any form of IPT, the focus is on problems in relationships that contribute to the onset, maintenance, and relapse of the disorder (Frank & Spanier, 1995; Klernan & Weissman, 1993). IPT thus is designed to improve current relationships and social functioning in general. Although IPT was originally developed to treat depression, the idea behind IPT for eating disorders is that as problems with relationships resolve, symptoms decrease, even though the symptoms are not addressed directly by the treatment (Swartz, 1999; Tantleff-Dunn, Gokee-LaRose, & Peterson, 2004).

How does IPT work? The hypothesized mechanism is as follows: (1) IPT reduces longstanding interpersonal problems; and (2) the resulting improvement of relationships makes people feel hopeful and empowered, and increases their self-esteem. These changes have four effects: First, they lead people to change other aspects of their lives, such as disordered eating; second, they lead to less concern about appearance and weight, and therefore less dieting and bingeing (Fairburn, 1997); third, as relationships improve, people have more social contact and hence less time to engage in disordered eating behaviors; and finally, with less interpersonal stress, people don't need to expend as much effort on coping and have less need for bingeing and purging to manage their (less frequent) negative feelings.

Although IPT for anorexia has not yet been well researched, IPT for bulimia has been, and many studies have shown that it is an effective alternative to CBT for bulimia (Apple, 1999; Birchall, 1999; Fairburn, 1997, 2005). IPT may require more time than CBT to reduce symptoms, but at 1-year follow-up, its results are comparable to those with CBT (Fairburn et al., 1986, 1993; Wilfley et al., 1993). For example, Fairburn (1997) randomly assigned people with bulimia to one of three treatments: CBT, IPT, or behavior therapy (BT). All three treatments decreased participants' symptoms, but CBT was slightly more effective. Over time, however, the benefits of BT declined, while people in the CBT and IPT groups continued to improve. Other studies have reported similar findings (Agras, Walsh et al., 2000; Wilson et al., 2002).

Family Therapy

Prior to the 1970s, anorexia was treated psychodynamically, which was the type of psychological treatment most widely available at that time. But in the 1970s, psychiatrists Salvador Minuchin in the United States (Minuchin, Rosman, & Baker, 1978) and Mara Selvini Palazzoli in Italy (1974, 1988) began to treat girls and young women with anorexia using family therapy, treating the family as a system. As we saw in Chapter 4, systems therapy identifies the problem as maladaptive family interactional patterns and structures, and treatment is designed to change these patterns and roles. As with IPT, treatment does not specifically address the patient's eating and food issues. Family therapy for anorexia nervosa has been found to be most effective for young women and girls who live with their parents.

The most widely used family-oriented treatment for anorexia is called the *Maudsley approach* (Dare & Eisler, 1997; le Grange & Eisler, 2009; Lock et al., 2001), named after the hospital in which the treatment originated. This approach does not view the family as responsible for causing problems and in fact makes no assumptions about the causes of the disorder. Instead, the **Maudsley approach** focuses on the future by: (1) helping parents view the patient as distinct from her illness, and (2) supporting the parents as *they* figure out how to lead their daughter to eat so that she can proceed with her development to adulthood. The therapist asks the parents to unite to feed their daughter, despite her anxiety and protests. Once her weight is normal and she eats without a struggle, they gradually return control to her, and other family issues—including general ones of adolescent development—become the focus (Lock, 2004). The initial phase of treatment requires an enormous commitment on the part of the family: A parent must be home continuously to monitor the daughter's eating. Clearly, the Maudsley approach is not feasible for all families. But research results indicate that it is perhaps the most effective treatment for adolescents and young adults with anorexia (Keel & Haedt, 2008).

Psychiatric Hospitalization

In contrast to medical hospitalizations, psychiatric hospitalizations for eating disorders are often planned in advance, and they usually take place in units that specialize in treating people with eating disorders. Psychiatric hospitalization is recommended when less intensive treatments have failed to change disordered eating behaviors sufficiently. The hospital environment is a 24-hour community in which patients attend many different types of group therapy, including groups focused on body image, coping strategies, and relationships with food. These groups can decrease the isolation and shame patients may feel and give patients an opportunity to try out new ways of relating. Hospitalized patients also receive individual therapy and usually some type of family therapy; medication may also be administered, if deemed appropriate.

The short-term goals of psychiatric hospitalization for anorexia and bulimia include increasing the individual's weight to the normal range, establishing a normal eating pattern (three full meals and two snacks per day), curbing excessive exercise, and beginning to change irrational, maladaptive thoughts about food, weight, and body shape. For those who purge or otherwise try to compensate for their caloric intake, an additional goal is to stop or at least reduce such compensatory behaviors.

Altrendo/Getty Images

One type of family therapy for people with anorexia is the Maudsley approach. The first step of this family treatment is to empower the parents to figure out how best to lead their daughter to resume normal eating.

Maudsley approach

A family treatment for anorexia nervosa that focuses on supporting parents as they determine how to lead their daughter to eat appropriately.

Psychiatric hospitalization can improve eating symptoms and help to change distorted thoughts about food, weight, and body. But, in many cases, these positive changes are not enduring. Twelve months after discharge from a psychiatric hospitalization, 30–50% of patients relapse (Pike, 1998). Consider that in 1 year, Marya Hornbacher was hospitalized three times. Why is there such a high relapse rate? There are various explanations. One is that some patients are reluctant to change their behaviors, and they accept the intensive treatment for health reasons or because of pressure from family members—but once out of the hospital, they are not willing to continue the changes they began. For example, each time Hornbacher was released from the hospital, she reverted to her old eating behaviors. Some researchers have examined the amount of weight gained during hospitalization for anorexia. Patients who gain more weight during their hospitalizations are likely to fare better 1 year later. This finding could mean that patients who are more motivated to improve will gain more weight while in the hospital; alternatively, it could mean that a higher level of weight gain in and of itself starts an upward spiral of recovery (Lund et al., 2009).

A second reason for the high relapse rate after psychiatric hospitalization is that some patients do not receive appropriate outpatient care after they leave the hospital. This lack of care makes it more difficult for them to learn how to sustain their changed eating, weight, and views about their bodies when they are not in a supervised therapeutic environment.

A third reason for the high relapse rate focuses on economic pressures from insurance companies, which have cut the approved length of hospital stays for people with eating disorders (and for those with psychological disorders in general). Psychiatric hospitalizations have become increasingly short, which reduces the amount of change that can realistically be accomplished during a stay. For instance, one study found that the average stay of a patient who is hospitalized for an eating disorder fell dramatically from 149.5 days in 1984 to 23.7 days in 1998 (Wiseman et al., 2001), and this decreased average length of stay may continue (Calderon et al., 2007). Psychiatric hospitalization no longer provides long-term treatment that yields enduring changes in eating habits and in thoughts and feelings about food and weight; instead, hospitalization now responds to symptom-related problems by stabilizing people when their medical or eating disorder symptoms approach a danger point (Wiseman et al., 2001). The “dose” of inpatient treatment is shorter, and so it is not surprising that the “response” is shorter-lasting and relapse is likely to occur. Marya Hornbacher described her experience:

In the last week of February, my vital [medical] signs stabilized and my [health] insurance pulled out. I was discharged on grounds of noncompliance and insufficient [insurance] coverage. Eating disorders are regarded, by the insurance companies, as temporary and cured once the heart speeds up a bit. I was returned to my parents’ house, batty and sicker than when I’d gone in. The tiny bit of weight I’d gained in the hospital scared me, and once discharged, I just stopped eating altogether.

(1998, p. 182)

Prevention Programs

Many mental health clinicians and researchers seek to *prevent* eating disorders, particularly for those individuals most at risk (Coughlin & Kalodner, 2006; Shaw et al., 2009; Stice & Hoffman, 2004): namely, those people who have some symptoms of an eating disorder but do not meet all the diagnostic criteria. Prevention programs often seek to challenge maladaptive beliefs about appearance and food and to decrease over-eating, fasting, and avoidance of some types of foods. Prevention programs may take place as a single session or multiple sessions, may take the form of presentations or workshops, or may even be provided via the Internet (Zabinski et al., 2001, 2004).

At least under some circumstances, such programs can be helpful. Meta-analyses have found that certain aspects of prevention programs (such as multiple sessions rather than a single session) were associated with less disordered eating in participants, compared to those in a control group (Stice & Shaw, 2004; Stice, Shaw, & Marti, 2006). Unfortunately, not all studies and reviews find prevention programs to be effective (Pratt & Woolfenden, 2002).

FEEDBACK LOOPS IN TREATMENT: Eating Disorders

With all eating disorders, successful treatment should resolve medical crises and normalize eating and nutrition, whether directly or indirectly. For a person with anorexia, this means increasing her eating. Better nutrition means improved brain functioning (neurological factor) and cognitive functioning (psychological factor). For a person with bulimia, it means normalizing her meals—making sure that she is not only eating adequately throughout the day but also getting enough of the various food groups. Eating in this way will decrease the likelihood of extreme hunger, binges, or eating that feels out of control (psychological factor) (Shah et al., 2005).

In most cases, enduring changes in eating arise from changes in the way the individual thinks about food, her beliefs about weight, appearance, femininity, efficacy, and control. These enduring changes may come about, in part, through CBT (psychological factor). In addition, the individual is not isolated from her social context. The support of family and friends and the improved quality of these relationships, which may arise from IPT or family therapy (social factor), can help her reject an overvaluation of appearance, weight, and body shape. Improved family interaction patterns can increase mood and satisfaction with relationships, which can decrease the level of attention that the person pays to cultural pressures toward an ideal body shape (psychological factor). The feedback loops involved in treating eating disorders are shown in Figure 10.8.

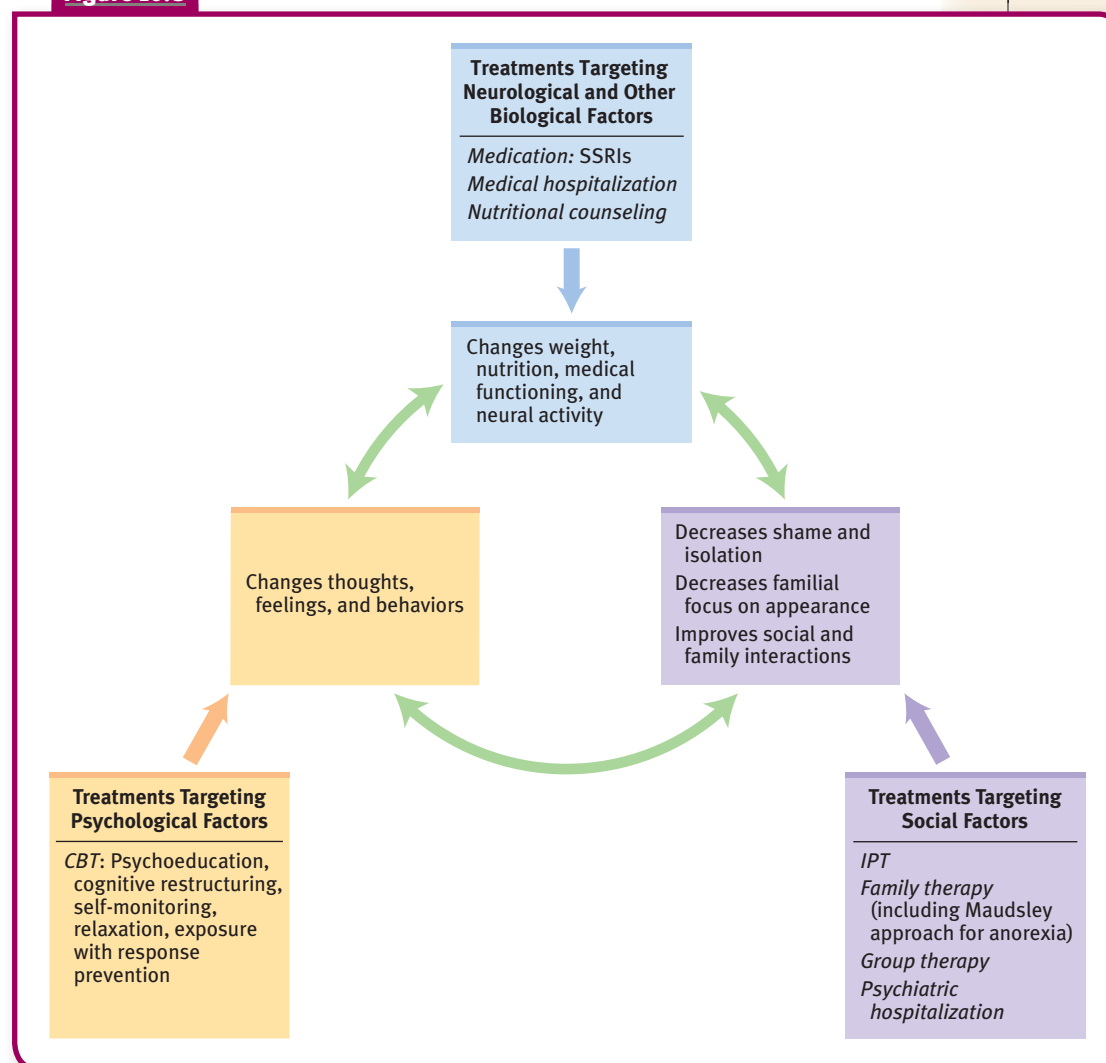

Figure 10.8

Key Concepts and Facts About Treating Eating Disorders

- The treatments that target neurological and other biological factors include:
 - nutritional counseling to improve eating (and can also correct erroneous information about food and weight);
 - medical hospitalization for significant medical problems related to the disorder; and
 - medication to address some symptoms of the eating disorder and of anxiety and depression. Specifically, SSRIs may help prevent relapse in those with anorexia and can decrease symptoms of bingeing and purging in those with bulimia.
- The primary treatment that targets psychological factors is CBT, which is the treatment of choice for eating disorders. CBT addresses maladaptive thoughts, feelings, and behaviors that impede normal eating, promote bingeing and purging, and lead to body image dissatisfaction. CBT may include exposure with response prevention and help patients develop new coping strategies.
- Treatments that target social factors include:
 - interpersonal therapy, which is designed to improve the patient's relationships; as relationships become more satisfying, the eating disorder symptoms diminish;
 - family therapy, particularly the Maudsley approach, which can be helpful for adolescents with anorexia who live at home. Parents figure out how to feed their child, despite her protests, until she eats normally and without a struggle;
 - psychiatric hospitalization, which provides supervised mealtimes to increase normal eating, and a range of therapeutic groups to address various psychological and social factors (such as irrational beliefs about food and weight and social problems), plus individual therapy and possibly medication;
 - prevention programs, which have the goal of preventing eating disorders from developing, particularly in high-risk individuals.

Follow-up on Marya Hornbacher

Marya Hornbacher's first memoir, *Wasted*, was written when she was 23 years old. Within a year of its publication, she was diagnosed with a rapid cycling form of bipolar disorder (see Chapter 6 for a discussion of bipolar disorder). Hornbacher spent the next 10 years struggling with alcohol dependence and bipolar disorder; her struggles are recounted in her subsequent memoir, *Madness: A Bipolar Life* (2008). Although the flagrant symptoms of eating disorders were mostly behind her at the close of *Wasted*, in her later memoir she reported occasional periods of restricting or purging as she struggled with manic episodes and mixed episodes. She recounts that these periods of disordered eating were attempts to regulate her extreme moods. Her experiences highlight the frequent comorbidity among people with eating disorders.

SUMMING UP

Summary of Anorexia Nervosa

The hallmark of anorexia nervosa is a refusal to maintain a healthy weight; DSM-IV-TR defines the weight cutoff as less than 85% of expected body weight. Other criteria include an intense fear of becoming fat or gaining weight, distortions in body image, and amenorrhea. DSM-IV-TR includes two types of anorexia: restricting and binge-eating/purging.

Anorexia can lead to significant medical problems, most importantly muscle wasting (particularly of heart muscle), low heart rate, low blood pressure, loss of bone density, and decreased metabolism. Other symptoms include irritability, headaches, fatigue, and restlessness. All methods of purging—vomiting,

diuretics, laxatives, and enemas—can cause dehydration. Starvation also leads to various psychological and social problems.

Critics of the DSM-IV-TR diagnostic criteria for anorexia point out that the criteria of low weight and amenorrhea are not highly associated with general medical status, prognosis, or outcome. Also, the two types of anorexia—restricting and binge-eating/purging—may better represent stages of the disorder rather than distinct paths it can take.

Thinking like a clinician

Since the age of 12, Lee has been very thin, in part because of hours of soccer practice weekly. Now, at the age of 17, Lee eats very little (particularly staying away from foods high in fat), continues exercising, and gets

angry when people comment about weight. What would you need to know to determine whether Lee has anorexia nervosa? If Lee does have anorexia, what would be some possible medical problems that might arise? What if Lee were male—would it change what you'd need to know to make the diagnosis? Explain your answer.

Summary of Bulimia Nervosa

Bulimia nervosa is characterized by recurrent episodes of binge eating followed by inappropriate efforts to prevent weight gain. DSM-IV-TR specifies two types of bulimia: the purging type (which is characterized by vomiting or the use of diuretics, laxatives or enemas) and

the nonpurging type (which involves fasting or excessive exercise). Bulimia is twice as prevalent as anorexia, and much more common among women than men.

All purging methods can cause dehydration, which lead to electrolyte imbalances and possibly death. Chronic vomiting can lead to enlarged parotid and salivary glands, and can erode dental enamel. Chronic laxative use can lead to permanent loss of intestinal functioning.

Aspects of the DSM-IV-TR criteria for a diagnosis of bulimia have been criticized: The definition of “binge eating” is subjective, the purging/nonpurging distinction does not correlate meaningfully with course or prognosis, and bulimia and anorexia do not appear to be distinct disorders but rather may be different phases of the same disorder. Problems with the criteria for anorexia and bulimia are apparent in the prevalence of eating disorder not otherwise specified (EDNOS), which has a higher prevalence than anorexia and bulimia combined. One subset of patients with EDNOS have binge-eating disorder.

Thinking like a clinician

Tanya had been dieting, but after a month or so, she began to pig out toward bedtime. After the first few of these gorging sessions, she felt both physically uncomfortable and ashamed of herself, and she would make herself vomit. After about a week, though, she stopped throwing up; instead she began exercising for about an hour each day. This pattern of daily exercising and pigging out in the evening has persisted for about 6 months. Does Tanya have bulimia nervosa, EDNOS, or just disordered eating but no DSM-IV-TR diagnosis? What were the key factors that determined your answer?

Summary of Understanding Eating Disorders

It is particularly difficult for researchers to establish cause-and-effect relationships among the factors associated with eating disorders because the symptoms themselves—restricting, bingeing, purging, excessive exercise, malnourishment—create neurological (and other biological), psychological, and social changes.

Neurological factors associated with eating disorders include unusually low activity in the frontal, temporal, and parietal lobes, as well as the anterior cingulate cortex, the basal ganglia, and the cerebellum. However, these neural patterns may vary for specific types of anorexia, and may be affected by dieting. Patients with anorexia also have reduced gray

and white matter. People with anorexia and bulimia are not as responsive to serotonin, a neurotransmitter involved in mood, anxiety, and binge eating. Eating disorders tend to run in families and have substantial heritability, which indicates a role for genes.

Psychological factors related to eating disorders include: irrational thoughts and excessive concerns about weight, appearance, and food; binge eating as a result of the abstinence violation effect; positive and negative reinforcement of symptoms of eating disorders (restricting, bingeing, and purging); certain personality traits (perfectionism, harm avoidance, neuroticism, and low self-esteem); disinhibited eating triggered by the last supper effect, especially in restrained eaters; and comorbid disorders in female adolescents, particularly depression.

Social factors related to eating disorders include: Family members and friends who provide a model for eating, concern about weight, and focus on appearance through their own behaviors and responses to others. Cultural factors play a key role, as evidenced by the increased prevalence over time of bulimia and concern about weight that is part of anorexia. Specific cultural factors include a cultural ideal of thinness and repeated exposure—through the media—to this ideal, as well as the individual’s assimilation of this ideal.

Thinking like a clinician

Suppose scientists discover genes that are associated with eating disorders. What could—and couldn’t—you infer about the role of genetics in eating disorders? How could genes contribute to eating disorders if bulimia is a relatively recent phenomenon? In what ways does the environment influence the development of eating disorders? Why do only some people who are exposed to familial and cultural emphases on weight, food, and appearance develop an eating disorder?

Summary of Treating Eating Disorders

The treatments that target neurological and other biological factors include: nutritional counseling; medical hospitalization for significant medical problems related to the disorder; and medication to address symptoms of the disorder and of anxiety and depression. Specifically, SSRIs may help prevent relapse in those with anorexia and can decrease symptoms of bingeing and purging in those with bulimia.

The primary treatment that targets psychological factors is CBT, which is the

treatment of choice for eating disorders. CBT addresses maladaptive thoughts, feelings, and behaviors that impede normal eating, promote bingeing and purging, and lead to body image dissatisfaction. CBT may include exposure with response prevention and help patients develop new coping strategies.

Treatments that target social factors include IPT, which is designed to improve the patient’s relationships; as relationships become more satisfying, the eating disorder symptoms diminish. Family therapy, particularly with the Maudsley approach, can be helpful for adolescents with anorexia who live at home. Psychiatric hospitalization provides supervised mealtimes to increase normal eating and a range of therapeutic groups to address various psychological and social factors. Prevention programs have the goal of preventing eating disorders from developing, particularly in high-risk individuals.

Thinking like a clinician

Suppose your local hospital establishes an eating disorders treatment program. Based on what you have learned in this chapter, what services should they offer, and why? If your friend, who has bulimia nervosa, asked your advice about what type of treatment she should get, how would you respond, and why?

Gender and Sexual Disorders

Laura and Mike have been married for a couple of years. They generally get along well, but lately their relationship has been strained. They both work long hours and are tired when they get home. They spend weekends doing household chores or zoning out in front of the television or their computers. Laura and Mike aren't spending much quality time together, and their sex life has become nonexistent. They don't even snuggle with each other in bed anymore and rarely touch each other outside the bed. Their relationship has changed so much since they first started dating, when they were attracted to each other and enjoyed sexual relations. What went wrong, and what can they do to improve their relationship?

By its very nature, human sexuality emerges from a confluence of neuropsychosocial factors. Neurologically, sexuality relies on the actions of hormones and brain activity. Psychologically, sexuality arises from the desire to be sexual with a particular person, in a certain situation, at a specific moment. Fantasies and thoughts, body image, the subjective sense of being male or female—all of these factors and others influence sexuality. Similarly, concerns about reproduction, infertility, or sexually transmitted diseases and past experiences related to sex, such as sexual abuse or rape, also affect an individual's sexuality.

Woody Allen once commented that his favorite part of masturbation was the cuddling afterward. This joke only serves to emphasize that sexuality is ultimately social: It involves relationships. In fact, even during solitary masturbation, someone's thoughts and fantasies usually involve other people. Sexuality is influenced by general emotional satisfaction with a partner, how satisfied the partner has been, the context of a particular sexual encounter, moral and religious teachings about sexuality, and cultural views of appropriate sexual behavior (Malatesta & Adams, 2001). All of these conditions and circumstances are ultimately rooted in social factors.

Abnormalities in sexuality and sexual behavior are also influenced by neuropsychosocial factors. For instance, an individual's brain (and, as a result, his or her body) may not respond to sexual stimuli in the usual way or may respond sexually to stimuli that are not generally considered to be sexual in nature (such as shoes). Similarly, some individuals may have sexual fantasies that disturb them, or they may have difficulties with sexual functioning that lead

What is viewed as normal and abnormal sexuality is partly based on the cultural views of appropriate sexual behavior.

to distress or problems in their relationships. In addition, families, communities, or cultures determine which sexual fantasies, urges, and behaviors are considered “deviant” or “abnormal.” These socially defined sexual “abnormalities” differ across cultures and shift over time. For example, masturbation and oral sex were once considered to be deviant. More recently, homosexuality was considered a psychological disorder until 1973, when it was removed from the DSM. Moreover, like most other psychological problems and disorders, normal and abnormal sexuality and sexual behavior fall on a continuum. However, DSM-IV-TR uses the categorical approach to define sexual disorders; that is, according to DSM-IV-TR, sexual fantasies, urges, and behaviors are either normal or not normal.

As we’ll see in this chapter, the diagnosis of most—though not all—sexual disorders in DSM-IV-TR hinges on the patient’s experience of distress or impaired functioning as a result of the sexual symptoms (First & Frances, 2008). Simply having unusual or “deviant” sexual fantasies or engaging in unusual sexual behaviors is not generally sufficient for a diagnosis.

The diagnostic criteria for various disorders in the DSM-IV-TR category of sexual and gender disorders address neuropsychosocial factors. That said, some disorders have predominantly neurological and other biological criteria (the *sexual dysfunctions*) whereas others have primarily psychological and social criteria (the *paraphilias* and *gender identity disorder*). Let’s examine these disorders.

Gender identity

The subjective sense of being male or female, as these categories are defined by the person’s culture.

Gender identity disorder

A psychological disorder characterized by a cross-gender identification that leads the individual to be chronically uncomfortable with his or her biological sex.

Gender role

The outward behaviors, attitudes, and traits that a culture deems masculine or feminine.

Gender Identity Disorder

Last year, Mike became confused when his good friend, Sam, began to dress like and live as a woman. In fact, Sam was changing his name to Sandy and would, within the next couple of years, have surgery to acquire female genitals. Sam had dated girls occasionally in high school and seemed “normal,” so Mike didn’t know how to make sense of Sam’s change. Seeing Sam as a woman made Mike uncomfortable, and now they only saw each other occasionally. Mike told Laura about Sam’s change to Sandy, but he hasn’t told her about his feelings about the change. Mike found himself wondering what life—and sex—had been like for Sam, and what it was like now for Sandy. Mike surfed the Internet for reputable information about Sam’s condition, and discovered that it is called *gender identity disorder*.

What Is Gender Identity Disorder?

Like Sam, a small percentage of people who are born one sex (either a biological female or a biological male) do not feel comfortable with their corresponding gender identity. **Gender identity** is the subjective sense of being male or female, as these categories are defined by the person's culture. For instance, there are people like Sam, who have normal male sexual anatomy but *feel* as if they are female. Conversely, there are people with normal female anatomy who feel as if they are male. For people with these feelings, their sense of their gender identity does not correspond to their biological sex, a condition known as *cross-gender identification*. Such individuals are said to have a **gender identity disorder**, a cross-gender identification that leads them to be chronically uncomfortable with their biological sex. People with gender identity disorder are sometimes referred to as *transsexuals*.

People with gender identity disorder usually identify with the opposite biological sex in childhood, preferring to dress or play with toys in ways that are typical of children of the other gender. That is, they wish to behave in accordance with the gender role of the other sex; **gender role** refers to the outward behaviors, attitudes, and traits that a culture deems masculine or feminine. For instance, gender roles for females often allow a wider variety of emotions (anger, tears, and fear) to be displayed in public than do gender roles for males; in contrast, gender roles for males often allow more overtly aggressive or assertive behaviors than do gender roles for females. An individual with gender identity disorder desires to adopt the gender role of the opposite sex not because of perceived cultural advantages of becoming the other sex, but because the opposite gender role is consistent with the person's sense of self.

In children, gender identity disorder is not simply "tomboyishness" in girls or "sissy" behavior in boys. Rather, gender identity disorder reflects a profound sense of identifying with the other sex, to the point of denying one's own sexual organs; moreover, girls with gender identity disorder report that they don't want to develop breasts or menstruate. Most children diagnosed with gender identity disorder, however, do not continue to have the disorder into adulthood, although a sizable number may identify themselves as homosexual when adults (American Psychiatric Association, 2000; Drummond et al., 2008; Green, 1987; Zucker, 2005; Zucker & Bradley, 1995). For instance, studies of boys with gender identity disorder have found that only 2–12% had gender identity disorder as adults. However, 40–80% of boys with gender identity disorder reported being bisexual or homosexual in adulthood (the wide range noted here is due, in part, to the fact that different studies define adult sexuality in different ways); the number of girls with gender identity disorder in childhood who have been followed into adulthood is too small to obtain reliable statistics (Zucker, 2005). Thus, having a diagnosis of gender identity disorder in childhood is generally a poor predictor of the disorder persisting into adulthood. Some have criticized the childhood diagnosis as a way to pathologize early homosexual behavior or interest or a way to label with a mental illness those who don't conform to cultural norms of sex-appropriate behaviors (Hill et al., 2005; Langer & Martin, 2004).

Table 11.1 lists the criteria for gender identity disorder. Among adolescents and adults, symptoms may include discomfort from living publicly as their biological sex. In fact, these individuals may be preoccupied by the wish to *be* the other sex. They may take that wish further and live, at least some of the time, as someone of the other sex—dressing and behaving accordingly, whether at home or in public. Some adults with gender identity disorder have medical and surgical treatments to assume the appearance of the other sex.

Table 11.1 ▶ DSM-IV-TR Diagnostic Criteria for Gender Identity Disorder

A. A strong and persistent cross-gender identification (not merely a desire for any perceived cultural advantages of being the other sex). In adolescents and adults, the disturbance is manifested by symptoms such as a stated desire to be the other sex, frequent passing as the other sex, desire to live or be treated as the other sex, or the conviction that he or she has the typical feelings and reactions of the other sex.

In children, the disturbance is manifested by four (or more) of the following:

- (1) repeatedly stated desire to be, or insistence that the person is, the other sex
- (2) in boys, preference for cross-dressing or simulating female attire; in girls, insistence on wearing only stereotypical masculine clothing
- (3) strong and persistent preferences for cross-sex roles in make-believe play or persistent fantasies of being the other sex
- (4) intense desire to participate in the stereotypical games and pastimes of the other sex
- (5) strong preference for playmates of the other sex.

B. Persistent discomfort with his or her sex or sense of inappropriateness in the gender role of that sex. In *children*, the disturbance is manifested by any of the following:

- In *boys*, assertion that his penis or testes are disgusting or will disappear or assertion that it would be better not to have a penis, or aversion toward rough-and-tumble play and rejection of male stereotypical toys, games, and activities;
- In *girls*, rejection of urinating in a sitting position, assertion that she has or will grow a penis, or assertion that she does not want to grow breasts or menstruate, or marked aversion toward normative feminine clothing.

In *adolescents* and *adults*, the disturbance is manifested by symptoms such as preoccupation with getting rid of primary and secondary sex characteristics (such as request for hormones, surgery, or other procedures to physically alter sexual characteristics to simulate the other sex) or belief that he or she was born the wrong sex.

C. The disturbance is not concurrent with a physical intersex condition [that is, a condition in which the individual has both male and female physical sexual characteristics].

D. The disturbance causes clinically significant distress or impairment.

Teena Brandon was born female, yet felt like a male on the inside and came to live as a man, though without having sex reassignment surgery. As an adult, Brandon was raped and later killed by young men after they discovered that Brandon was biologically female. Brandon's life was the subject of the documentary film *The Brandon Teena Story* and the feature film *Boys Don't Cry*.

Females have a wider range of acceptable "masculine" behavior and dress than males have of acceptable "feminine" behavior and dress. Women can wear men's clothes without risk of being labeled as deviant, whereas men who wear women's clothes (when not as part of a performance) are often considered to have something wrong with them.

The final two DSM-IV-TR criteria require that the symptoms do not arise because the person is an *intersex* individual (someone who was born with both male and female sexual characteristics) and that the symptoms cause significant distress or impair functioning. However, the distress experienced by someone with gender identity disorder often arises because of *other people's responses* to the cross-gender behaviors. For instance, a biological male child with gender identity disorder may be ostracized or made fun of by children or even teachers for consistently "playing girl games"—and thus the child feels distress because of the reactions of others. In contrast, for most disorders in DSM-IV-TR, the distress the individual feels arises directly from the symptoms themselves (e.g., distress that is caused by feeling hopeless, or being afraid in social situations).

Most adolescents and adults with gender identity disorder report having had symptoms of the disorder in childhood (even though most people who had gender identity disorder in childhood do not have it later in life), like the person in Case 11.1. And like Mike's friend Sam, some people with gender identity disorder seek to change their sexual anatomy to match their gender identity; such surgery is called *sex reassignment surgery* (discussed later in the chapter, in the section on treatment).

CASE 11.1 ► FROM THE INSIDE: Gender Identity Disorder

In her memoir, *She's Not There: A Life in Two Genders* (2003), novelist and English professor Jenny Finney Boylan (who was born male) describes her experiences feeling, since the age of 3, as if she were a female in a male body:

Since then, the awareness that I was in the wrong body, living the wrong life, was never out of my conscious mind—never, although my understanding of what it meant to be a boy, or a girl, was something that changed over time. Still, this conviction was present during my piano lesson with Mr. Hockenberry, and it was there when my father and I shot off model rockets, and it was there years later when I took the SAT, and it was there in the middle of the night when I woke in my dormitory at Wesleyan. And at every moment I lived my life, I countered this awareness with an exasperated companion thought, namely, Don't be an *idiot*. You're *not* a girl. Get over it.

But I never got over it.

[...] By intuition I was certain that the thing I knew to be true was something others would find both impossible and hilarious. My conviction, by the way, had nothing to do with a desire to be *feminine*, but it had everything to do with being *female*. Which is an odd belief for a person born male.

(pp. 19–21)

Most commonly, individuals with gender identity disorder are heterosexual relative to their gender identification. For instance, biological men who see themselves as women tend to be attracted to men, and thus feel as if they are heterosexual (Blanchard, 1989, 1990; Zucker & Bradley, 1995). Others are homosexual relative to their gender identification; a biological woman who sees herself as a man may be sexually attracted to men. However, some people with gender identity disorder are asexual—they have little or no interest in any type of sex.

As noted in Table 11.2 (along with other facts about gender identity disorder), gender identity disorder is about three times more common among biological males as biological females. One explanation for this difference is that in Western cultures, females have a wider range of acceptable "masculine" behavior and dress than males do of acceptable "feminine" behavior and dress. A woman dressed in "men's" clothes might not even get a second look, but a man dressed in "women's" clothes will likely be subjected to ridicule.

Table 11.2 ▶ Gender Identity Disorder Facts at a Glance

Prevalence
<ul style="list-style-type: none"> The prevalence of gender identity disorder is unknown, but believed to be low.
Comorbidity
<ul style="list-style-type: none"> In one survey of 31 patients who were diagnosed with gender identity disorder and had not yet begun the process of sex reassignment surgery, almost 75% had another psychiatric disorder at some point in their lives, most often either a mood disorder or a substance-related disorder (Hepp et al., 2005). However, only 39% had comorbid Axis I disorders after they began the sex reassignment process; this finding suggests that the previous high comorbidity was at least partly related to living as a gender that did not correspond to a person's gender identity.
Onset
<ul style="list-style-type: none"> Symptoms of cross-gender identity almost always begin in childhood. During adolescence, relationships with parents and peers often become particularly strained, and teenagers with gender identity disorder may become depressed (Di Ceglie et al., 2002).
Course
<ul style="list-style-type: none"> If symptoms persist into adulthood, they are likely to remain stable, leading many individuals to seek sex reassignment surgery.
Gender Differences
<ul style="list-style-type: none"> The incidence of those seeking sex reassignment surgery in some European countries is 1 of every 30,000 males and 1 of every 100,000 females, which suggests that gender identity disorder may be three times more common among males. Biological males with this disorder may be rejected by family and peers, may experience physical abuse, substance abuse, prostitution, AIDS, or poverty, and may drop out of school (Seil, 1996).
Cultural Differences
<ul style="list-style-type: none"> Cross-gender identification is not considered pathological in all cultures; in some Native American and traditional African cultures, such people have high status and are seen as especially spiritual (Jacobs, Thomas, & Lang, 1997; Langer & Martin, 2004; Roscoe, 1993).

Criticisms of the DSM-IV-TR Definition

Some critics of the DSM-IV-TR diagnosis of gender identity disorder point out that the criteria don't specify the nature of the "distress" that the disorder causes. As mentioned earlier, with gender identity disorder, distress usually arises because of other people's reactions to the cross-gender behaviors associated with the symptoms (Langer & Martin, 2004). For instance, suppose family members respond negatively—perhaps with anger—to an individual's cross-gender behaviors, even disowning him or her. Understandably, the person might then experience distress or impaired functioning. In this case, the distress or impaired functioning doesn't arise from the symptoms of gender identity disorder; it arises as a (often reasonable) response to the negative reactions of others.

In addition, some critics claim that the concept of gender in DSM-IV-TR is too narrow. Critics also argue that the concept of "appropriate" behavior (especially for males) is too constrained.

Understanding Gender Identity Disorder

We now know that the brains of adults with gender identity disorder are different in some respects from the brains of people who do not have the disorder. Moreover, various psychological and social factors are associated with gender identity disorder. But research so far has not determined whether these factors *contribute* to the disorder

or are early manifestations of the disorder. In the following sections we examine these neurological, psychological, and social factors.

Neurological Factors

Researchers know little about neurological factors that contribute to gender identity disorder. However, they have begun to document differences in specific brain structures in people who have the disorder versus those who do not, and have evidence that hormones during fetal development play a role in producing this disorder. In addition, genes can play a large role in contributing to this disorder.

Brain Systems and Neural Communication

The brains of transsexuals differ from typical brains in ways consistent with their gender identity. In particular, Kruijver and colleagues (2000) examined a specific type of neuron in a brain structure called the *bed nucleus of the stria terminalis* (which is often regarded as an extension of the amygdala). Typically, males have almost twice as many of these neurons as females do. In this study, the number of these neurons in the brains of male-to-female transsexuals was in the range typically found in female brains, and the number in the brains of female-to-male transsexuals was in the range typically found in male brains.

How might such brain alterations arise? Research suggests that prenatal exposure to hormones may affect later gender identity (Bradley & Zucker, 1997; Wallien et al., 2008; Zucker & Bradley, 1995). In particular, maternal stress during pregnancy could produce hormones that predispose a person to gender identity disorder (Zucker & Bradley, 1995). In rats, maternal stress raises the level of cortisol in both the pregnant rat and any male pups she is carrying. Such an increase in cortisol can disrupt the timing of prenatal developmental events in a way that leads to low levels of androgen in the fetus and changes certain brain areas (Ward, 1992; Zucker & Bradley, 1995, p. 155). The mother's male pups later exhibit less "male" behavior (less initiation of copulation, less rough play) and more "female" behavior (a sexual posturing typical of female but not male rats). One study found similar results in humans but with a different hormone, testosterone (which underlies many male sexual characteristics): Fetal levels of testosterone—measured from amniotic fluid—were positively associated with later stereotypical "male" play behavior in girls and, to a lesser extent, in boys; the higher the level of testosterone in the fluid, the more "male" play the children exhibited when they were between 6 and 10 years old (Auyeung et al., 2009).

Genetics

A hint that genetic factors contribute to gender identity disorder was reported by Sadeghi and Fakhrai (2000). These researchers described two 18-year-old female identical twins, both of whom had requested sex reassignment surgery. These young women had cross-dressed since childhood and had the hallmarks of gender identity disorder. That same year, Green (2000) reported ten pairs of close relatives (siblings or parent-child pairs) who had in common gender identity disorder. These case reports are intriguing, but they do not carry the force of full-scale studies such as the one conducted by Coolidge and colleagues (2002). These researchers studied 314 children who were either identical or fraternal twins and concluded that as much as 62% of the variance in gender identity disorder can be chalked up to genes! If this result is replicated, it will provide strong support for these researchers' view that the disorder "may be much less a matter of choice and much more a matter of biology" (p. 251). However, even in this study, almost 40% of the variance was ascribed to the effects of nonshared environment, and thus genes—once again—are not destiny.

In short, neurological factors—brain differences, prenatal hormones, and genetic predispositions—may contribute to gender identity disorder, but the presence of any one of these factors does not appear to be sufficient to lead to this disorder (Di Ceglie, 2000).

Psychological Factors: A Correlation With Play Activities?

In general, correlational studies have found that boys are more likely than girls to engage in rough-and-tumble play and to have a higher activity level. Biological boys

with gender identity disorder, however, do not have as high an activity level as their counterparts without the disorder. Similarly, biological girls with gender identity disorder are more likely to engage in rough-and-tumble play than are other girls (Bates, Bentler, & Thompson, 1973, 1979; Zucker & Bradley, 1995). Both boys and girls with gender identity disorder are less likely to play with same-sex peers; instead, they seek out, feel more comfortable with, and feel themselves to be more similar to children of the other sex (Green, 1974, 1987). Of course, such findings should be interpreted with caution, for two reasons: (1) These very characteristics are part of the diagnostic criteria for gender identity disorder in children, so it is not at all surprising that these behaviors are correlated with having the disorder; (2) a diagnosis of gender identity disorder in childhood does not usually persist into adulthood. Thus, beyond symptoms that are part of the criteria for gender identity disorder, no psychological factors are clearly associated with the disorder.

Social Factors: Responses From Others

Social factors may be associated with gender identity disorder, but such factors are unlikely to be sufficient to *cause* the disorder (Bradley & Zucker, 1997; Di Ceglie, 2000). Nevertheless, one study found that mothers of boys with gender identity disorder remarked on their sons' physical beauty, which may have led the mothers to interact differently with these sons, treating them more as girls (Zucker et al., 1993). As shown in Figure 11.1(a), college students rated photographs of boys with gender identity disorder as cuter and prettier than photos of boys without the disorder; in contrast, Figure 11.1(b) shows that girls with gender identity disorder were rated as less attractive than girls who did not have the disorder (Zucker et al., 1993). These contrasting ratings of physical appearance may reflect the prenatal influence of hormones: Biological boys may have been exposed to more female hormones in the womb, leading to the feminization of their facial features; conversely, biological girls may have been exposed to more male hormones in the womb, leading to the masculinization of their facial features. In turn, the feminized or masculinized facial features may lead others to interact differently with people who then develop this disorder.

Figure 11.1

11.1 ► Physical Attractiveness Ratings of Children With Gender Identity Disorder

(a) Viewing photographs, college students rated boys with gender identity disorder as more attractive than boys without this disorder. (b) Girls with gender identity disorder were considered to be less attractive than girls who did not have the disorder (Zucker et al., 1993).

Source: Adapted from Zucker & Bradley, 1995.

Given how little is known about the neurological, psychological, and social factors that contribute to gender identity disorder, we cannot comment on the nature of any feedback loops among them.

Treating Gender Identity Disorder

Treatments for gender identity disorder can target neurological (and other biological), psychological, or social factors.

Targeting Neurological and Other Biological Factors: Altered Appearance

One way for people with gender identity disorder to achieve greater congruence between the gender they feel themselves to be and the sex of their bodies is to alter some or all of their biological sexual characteristics. This sort of treatment may involve taking hormones: In biological women, taking androgens (i.e., male sex hormones) will lower the voice, stop menstruation, and begin facial hair growth. In biological men, taking estrogen or progesterone (i.e., female sex hormones) will enlarge breasts, and redistribute fat to the hips and buttocks.

Some people with gender identity disorder go a step further and have **sex reassignment surgery**, a procedure in which the genitals (and breasts, for biological women) are surgically altered to appear like those of the other sex. Sex reassignment surgery for biological males involves creating breasts and removing most of the penis and testes and then creating a clitoris and vagina. For biological females, surgery involves the removal of breasts, ovaries, and uterus and then creating a penis. Patients may also have subsequent surgeries to make their facial features more similar to those of the other sex. These surgical treatments can be prohibitively expensive, however.

Sex reassignment surgery is technically more effective for biological men than for biological women, in part because it is difficult to create an artificial penis that provides satisfactory sexual stimulation (Steiner, 1985). Regardless of biological sex, however, most people who have gender identity disorder are satisfied with the outcome of their sex reassignment surgery, despite possible difficulty in attaining orgasm (Cohen-Kettenis & Gooren, 1999; Smith et al., 2005). However, up to 10% of people who have this surgery (depending on the study) later regret it (Landen et al., 1998; Smith, Van Goozen, & Cohen-Kettenis, 2001). Factors associated with a less positive outcome after surgery are having unsupportive family members (Landen et al., 1998), having a comorbid psychological disorder (Bodlund & Kullgren, 1996; Midence & Hargreaves, 1997; Smith et al., 2005), and being psychologically unstable prior to the surgery (Smith et al., 2005).

In an effort to reduce the proportion of people who come to regret having sex reassignment surgery, those contemplating it are usually carefully evaluated beforehand regarding their emotional stability and their expectations of what the surgery will accomplish. A careful diagnostic evaluation and a long period of cross-dressing are required by most facilities before sex reassignment surgery is done.

Targeting Psychological Factors: Understanding the Choices

Treatment that targets psychological factors helps those with gender identity disorder not only to understand themselves and their situation but also to be aware of their options and goals (regarding living publicly as the other sex); treatment also provides information about medical and surgical options. Such treatment is typically provided by mental health clinicians specially trained in diagnosing and helping people with gender identity disorder. These clinicians also help patients identify and obtain treatment for any other mental health concerns, such as depression or anxiety (Carroll, 2000). For those who choose to live part-time or

Ian Spratt

Caroline Cossey, born Barry Cossey, increasingly felt during adolescence that although she had a male body, she was a female inside. When 20 years old, after a couple of years of taking female hormones and living as a woman, Cossey had sex reassignment surgery and later became a model and actress.

Sex reassignment surgery

The procedure in which an individual's genitals (and breasts, for biological women) are surgically altered to appear like those of the other sex.

full-time as the other sex, the clinician helps them discover whether doing so feels more consistent with how they feel and how they see themselves. Moreover, the clinician helps the patient with problem solving related to living as the other sex—identifying and developing possible solutions to issues that might arise regarding other people's responses.

Targeting Social Factors: Family Support

Family members of those with gender identity disorder may not understand the disorder or know how to be supportive. Educating the family about gender identity disorder and standard family therapy techniques that focus on communication (see Chapter 4) can help family members develop more effective ways to discuss problems.

In addition, groups for people with gender identity disorder can provide support and information. Group therapy may also focus on relationship difficulties or problems that may arise as a result of living as the other sex, such as experiencing sexual harassment for those newly living as a woman, or being taunted by other men for those newly living as a man (Di Ceglie, 2000).

In sum, treatment for gender identity disorder first targets psychological factors—helping individuals determine whether they want to live as the other sex. If they decide to do so, then treatment targeting social factors comes into play, to address problems with family members and interactions with other people in general. Finally, treatment targeting neurological and other biological factors is provided when individuals wish to have medical or surgical procedures.

Key Concepts and Facts About Gender Identity Disorder

- Gender identity disorder is characterized by a persistent cross-gender identification that leads to chronic discomfort with one's biological sex. Symptoms of gender identity disorder often emerge in childhood, but most children diagnosed with the disorder no longer have the disorder by the time they become adults. However, most adults with gender identity disorder report that their symptoms began in childhood.
- In children, symptoms of gender identity disorder include cross-dressing and otherwise behaving in ways typical of the other sex, such as engaging in other-sex types of play, choosing other-sex playmates, and even claiming to be the other sex. In adults, symptoms include persistent and extreme discomfort from living publicly as their biological sex, which leads many to live (at least some of the time) as someone of the other sex.
- Criticisms of the diagnostic criteria in DSM-IV-TR for this disorder point to the overly narrow concept of gender and appropriate behavior (particularly for males) and the ambiguous requirement about distress. With gender identity disorder, the person's distress often arises because of other people's reactions to the cross-gender behaviors.
- Some brain areas in adults with gender identity disorder are more similar to the corresponding brain areas of members of their desired sex than they are to those of their biological sex. Results from animal studies suggest that one explanation for this disorder is that prenatal exposure to hormones causes the brain to develop in ways more similar to the other sex, although the sexual characteristics of the body are unchanged. Beyond symptoms that are part of the diagnostic criteria for the disorder, no psychological or social factors are clearly associated with the disorder.
- Treatments may target neurological (and other biological), psychological, or social factors:
 - Treatments that target neurological (and other biological) factors include hormone treatments and sex reassignment surgery.
 - Treatments that target psychological factors include psychoeducation, helping the patient choose among gender-related lifestyle options, and problem solving about potential difficulties.
 - Treatments that target social factors include family education, support groups, and group therapy.

Making a Diagnosis

- Reread Case 11.1 about Jenny Boylan, and determine whether or not her symptoms meet the criteria for gender identity disorder. Specifically, list which criteria apply and which do not. If you would like more information to determine whether the diagnosis fits, what information—specifically—would you want, and in what ways would the information influence your decision?

Paraphilias

One of the reasons that Mike was so disturbed about Sam's transformation into Sandy was that it reminded Mike of his secret pastime during his teenage years: He'd secretly "borrow" some of his older sister's clothes from her room, dress up as a girl, and admire himself in front of the mirror. He'd found this extremely erotic, but also terrifying. He worried that he'd get caught and felt that it somehow wasn't "right." Throughout his adulthood, Mike struggled to overcome his urge to dress in women's clothes, usually successfully. During most of his marriage to Laura, he'd managed to keep this urge at bay, and he never told his wife about it. However, once he heard about Sam, his urge became stronger—which affected his relationship with Laura because he thought it best to avoid sexual relations with her until he felt more in control of himself. He'd felt alone in his worries and concerns until he frequented online chat rooms. Now he's spending a lot of time "chatting" with other men who like to cross-dress; he bought some women's clothes (which he kept hidden) and puts them on and masturbates when Laura is out. What's going on with Mike? To find out, we need to consider another category of sexual disorders, called *paraphilias*.

What Are Paraphilias?

Gender identity disorder focuses on the mismatch between an individual's gender identity and biological sex. In contrast, the DSM-IV-TR set of **paraphilias** (from the Greek *para-*, meaning "beside" or "beyond," and *philos*, meaning "fondness" or "love") focuses on "deviant" fantasies, objects, or behaviors that play a role in sexual arousal. Specifically, a paraphilia is characterized by intense recurrent sexual fantasies or urges related to:

- nonconsenting partners or children,
- nonhuman objects (such as women's shoes), or
- suffering or humiliating oneself or one's partner; the diagnosis of a paraphilia would apply only when such experiences are not part of sexual role-playing.

These fantasies, urges, or behaviors together form a predictable pattern of arousal that is consistent for an individual (referred to as an *arousal pattern*). To be considered more than a normal variation in sexual fantasies, urges, or behaviors, this arousal pattern must:

- interfere with the ability for mutual sexual activity involving affection,
- impair functioning in some other way,
- cause significant distress, or
- involve a person who did not consent (as when exhibitionists "flash" unsuspecting strangers).

In addition, the diagnostic criteria for all paraphilias require that the arousal pattern has been present for at least 6 months (American Psychiatric Association, 2000). However, the arousal pattern doesn't necessarily affect all areas of functioning—people with a paraphilia may not be impaired at work or even necessarily in their family life.

Sexuality—both normal and abnormal—is best thought of as being represented by a continuum, but DSM-IV-TR uses a categorical approach, which means drawing a line to separate "normal" from "abnormal." For some paraphilias, DSM-IV-TR draws the line at the point where the sexual arousal pattern causes significant distress or impairs functioning. Someone who becomes aroused in response to pornography or in response to particular items of clothing, for instance, would not be diagnosed as having a paraphilia unless this arousal pattern caused significant distress or impaired functioning.

The specific arousal patterns of the types of paraphilias are listed in Table 11.3, along with their DSM-IV-TR diagnostic criteria. Paraphilic disorders are often classified into two groups: those that involve nonconsenting individuals, and those

Paraphilia

A sexual disorder characterized by deviant fantasies, objects, or behaviors that play a role in sexual arousal.

that involve objects or consenting adults. Paraphilic disorders are almost exclusively diagnosed in men; the only paraphilia observed in a significant percentage of women is *sexual masochism*. Because of the extremely high prevalence of the other paraphilias

Table 11.3 ▶ Paraphilias: An Overview and the DSM-IV-TR Diagnostic Criteria

Disorder	Specific Sexual Fantasies, Urges, or Activities to Enhance Sexual Arousal	DSM-IV-TR Diagnostic Criteria
Exhibitionism	Exposing genitals to an unsuspecting stranger	A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving exposing one's genitals to an unsuspecting stranger. B. The person has acted on these urges, or the sexual urges or fantasies cause marked distress or interpersonal difficulty.
Voyeurism	Observing an unsuspecting person who is disrobing or having sex	A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving the act of observing an unsuspecting person who is naked, in the process of disrobing, or engaging in sexual activity. B. The person has acted on these urges, or the sexual urges or fantasies cause marked distress or interpersonal difficulty.
Frotteurism	Touching or rubbing against a nonconsenting person	A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving touching and rubbing against a nonconsenting person. B. The person has acted on these urges, or the sexual urges or fantasies cause marked distress or interpersonal difficulty.
Pedophilia	Sexual activity with a prepubescent child	A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving sexual activity with a prepubescent child or children (generally age 13 years or younger). B. The person has acted on these urges, or the sexual urges or fantasies cause marked distress or interpersonal difficulty. C. The person is at least age 16 years and at least 5 years older than the child or children in Criterion A.
Sexual Sadism	Inflicting psychological or physical pain on another person	A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving acts (real, not simulated) in which the psychological or physical suffering (including humiliation) of the victim is sexually exciting to the person. B. The person has acted on these urges with a nonconsenting person, or the sexual urges or fantasies cause marked distress or interpersonal difficulty.
Sexual Masochism	Being humiliated, bound, or made to suffer in other ways	A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving the act (real, not simulated) of being humiliated, beaten, bound, or otherwise made to suffer. B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in functioning.
Fetishism	Using a nonliving object to become aroused	A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving the use of nonliving objects (such as female undergarments). B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in functioning. C. The fetish objects are not limited to articles of female clothing used in cross-dressing (as in Transvestic Fetishism, below) or devices designed for the purpose of tactile genital stimulation (such as a vibrator).
Transvestic Fetishism	Cross-dressing (dressing in clothes of the other gender for sexual arousal)	A. Over a period of at least 6 months, in a heterosexual male, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors that involve cross-dressing. B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impair functioning.

Paraphilias include deviant sexual fantasies, urges, and activities that can be classified into three types: Those that involve nonconsenting partners or children (in **purple**); those that involve suffering or humiliating oneself or a partner (in **gray**); and those that involve nonhuman animals or objects (in **yellow**). Note that sexual sadism involves nonconsenting people. Nonetheless, DSM-IV-TR groups sexual sadism with sexual masochism, rather than with the other paraphilias that involve nonconsenting people. Note also that the specifics of Criterion B—distress, impaired functioning, interpersonal problems, or acting on the sexual fantasies and urges—vary across the paraphilic disorders, depending in part on the whether the disorder involves nonconsenting individuals.

Source: Adapted from American Psychiatric Association, 2000; McNulty, Adams, & Dillon, 2001, p. 751. For more information see the Permissions section.

among men, in this section we use the masculine pronouns (e.g., *him*) when discussing patients with these disorders. (In the section on understanding paraphilias, we will examine possible reasons for this extreme gender difference.)

Mental health researchers believe that, based on the number of Web sites and on-line chat rooms, the prevalence of paraphilic disorders is higher than had been previously thought, but the actual prevalence is unknown. Most research on paraphilias has been conducted with men whose disorders involve nonconsenting individuals (such as child molesters, rapists, and exhibitionists) and who have come to the attention of mental health clinicians and researchers through the criminal justice system or at the urging of family members. We examine that type of paraphilias first.

Paraphilias Involving Nonconsenting Individuals

The common feature of the paraphilic disorders discussed in this section is that the person with the disorder has sexual fantasies, urges, or behaviors that involve nonconsenting individuals—children in the case of pedophilia. Specifically, if the patient has recurrent fantasies or urges involving a nonconsenting person *but does not act on them*, a diagnosis of the paraphilic disorder is given only if the fantasies and urges cause significant distress or interpersonal difficulties. In contrast, if the man did act on those recurrent fantasies and urges with a nonconsenting individual, the diagnosis would be made, even if the patient did not experience distress or other interpersonal difficulties. For instance, someone who “flashes” others, who molests children, or who sadistically sexually assaults victims would be diagnosed with a paraphilic disorder if the duration criterion (at least 6 months) for the behavior were met.

Thus, men who engage in some criminal sexual behaviors could qualify for the diagnosis of a paraphilia, which creates confusion about what constitutes criminal behavior versus mental illness. However, psychiatrists who helped to create the diagnostic criteria for paraphilias in DSM-IV-TR point out that they never intended to allow paraphilias to be diagnosed solely on the basis of sexual *behaviors*, because doing so “blurs the distinction between mental disorder and ordinary criminality” (First & Frances, 2008, p. 1240). This problem is likely to be addressed in the next edition of the DSM, DSM-V.

Exhibitionism: Physically Exposing Oneself

The paraphilia **exhibitionism** is characterized by sexual fantasies, urges, or behaviors that hinge on a person’s exposing his genitals to a stranger, usually as a surprise (see Table 11.3). Moreover, to be considered a disorder, the man must either experience distress or relationship problems as a result of the fantasies and urges or have actually exposed himself. People who expose themselves for money (such as nude dancers or artists’ models) are not considered exhibitionists because they do so for compensation, not for sexual arousal (McAnulty, Adams, & Dillon, 2001).

A man with exhibitionism typically gets an erection and may masturbate while exposing himself. Men with this disorder commonly report that they don’t intend to frighten or shock strangers, but hope that strangers will enjoy or be aroused by seeing their genitals (Lang et al., 1987; Langevin et al., 1979). Men with exhibitionism may rehearse beforehand; they may achieve orgasm during the exhibitionistic episode or later, when they think about it. One study found that, over the course of his life, the typical man with this disorder had “flashed” an average of 514 people (Abel et al., 1987). (However, some very active men skew the average; the median number of people flashed is 34.) Case 11.2 examines one man’s experience.

CASE 11.2 ► FROM THE OUTSIDE: Exhibitionism

Tom was a 39-year-old married businessman who was referred for . . . assessment because of persistent dependence on phone sex, video pornography, and compulsive masturbation despite relapse prevention sex offender group therapy and individual psychodynamic psychotherapy. Tom had been arrested for exhibitionism 2 years before as well and was on probation. In an attempt to control his urges to expose himself, he had made a behavioral contract with

Exhibitionism

A paraphilic disorder in which sexual fantasies, urges, or behaviors hinge on exposing one’s genitals to a stranger, usually as a surprise.

his wife that he would immediately tell her if he had urges to expose himself or if he had done so. He had agreed to take a lie detector test any time she requested it. He had a signed agreement with his wife that he would live separately from her if his exhibitionism relapsed. He reported that this behavioral contracting intervention was helpful in assisting him to refrain from exposing himself, but had not stopped his [other compulsive sexual behaviors]. He also still had recurrent urges to expose himself as well. He reported that his hypersexual fantasies, urges, and activities distracted him for 1 to 2 hours a day although he currently denied a high frequency of genital/sexual behavior.

(Kafka, 2000, pp. 493–494)

Voyeurism: Watching Others

Voyeurism is the paraphilia characterized by sexual fantasies, urges, or behaviors that involves *observing* someone who is in the process of undressing, is nude, or is engaged in sexual activity. The person being watched has neither consented to nor is aware of being observed (see Table 11.3). As with exhibitionism, for voyeurism to be a disorder, the person's urges and fantasies must cause distress or relationship problems, or the person must have acted on those fantasies and urges.

The voyeur rarely has physical contact with the observed person. Moreover, voyeurism is distinguished from looking at pornography or watching nude dancing; voyeurism involves observing someone *who does not know that he or she is being observed*. A man with this disorder might use binoculars to “spy” on a woman, masturbating while observing her through her window as she undresses, or might plant hidden cameras and watch the video later or via an Internet feed.

Frotteurism: Touching a Stranger

Frotteurism (from the French, *frotter*, “to rub”) is characterized by recurrent, intense, sexually arousing fantasies, sexual urges, or behaviors that involve touching or rubbing against a nonconsenting person (see Table 11.3). As with exhibitionism and voyeurism, the urges and fantasies must cause distress or relationship problems, or the man must have acted on those fantasies and urges. This diagnosis has two types: men who like to rub, and men who like to touch (“touchers”). On crowded public transportation, men with frotteurism try to stand or sit next to attractive females and rub their genitals against the victims' buttocks, thighs, or crotch, often while fantasizing that they are having consensual sex, as Charles, in Case 11.3, did. When discovered, men with frotteurism flee from the train or bus.

CASE 11.3 ► FROM THE OUTSIDE: Frotteurism

Charles was 45 when he was referred for psychiatric consultation by his parole officer following his second arrest for rubbing up against a woman in the subway. According to Charles, he had a “good” sexual relationship with his wife of 15 years when he began, 10 years ago, to touch women in the subway. A typical episode would begin with his decision to go into the subway to rub against a woman, usually in her 20s. He would select the woman as he walked into the subway station, move in behind her, and wait for the train to arrive at the station. He would be wearing plastic wrap around his penis so as not to stain his pants after ejaculating while rubbing up against his victim. As riders moved on to the train, he would follow the woman he had selected. When the door closed, he would begin to push his penis up against her buttocks, fantasizing that they were having intercourse in a normal, noncoercive manner. In about half the episodes, he would ejaculate and then go on to work. If he failed to ejaculate, he would either give up for that day or change trains and select another victim. According to Charles, he felt guilty immediately after each episode, but would soon find himself ruminating about and anticipating the next encounter. He estimated that he had done this about twice a week for the last 10 years and thus had probably rubbed up against approximately a thousand women.

(Spitzer et al., 2002, pp. 164–165)

David Young-Wolff/Photo Edit

People with voyeurism tend not to have physical contact with the people they observe.

Voyeurism

A paraphilia characterized by sexual fantasies, urges, or behaviors that involve observing someone who is in the process of undressing, is nude, or is engaged in sexual activity, when the person being observed has neither consented to nor is aware of being observed.

Frotteurism

A paraphilia characterized by recurrent, intense, sexually arousing fantasies, sexual urges, or behaviors that involve touching or rubbing against a nonconsenting person.

Pedophilia: Sexually Abusing Children

Child sexual abuse is a crime, but the DSM-IV-TR diagnosis for those who fantasize about, have urges, or actually engage in sexual activity with a child (typically one who has not yet gone through puberty) is **pedophilia** (see Table 11.3). For this diagnosis, the person with pedophilia must be at least 16 years old, and at least 5 years older than the child. Thus, someone is diagnosed with pedophilia if he has had sexual activity with a child (and so would also be considered a *child molester*) or if he has sexual fantasies about or urges to do so and these impulses significantly impair his relationships or cause distress. Someone with pedophilia may or may not sexually molest children; a child molester may or may not be diagnosed with pedophilia, depending on the duration of the related fantasies, urges, or behaviors (Camilleri & Quinsey, 2008).

The sexual behaviors range from fondling to oral-genital contact to penetration. Approximately 25% of victims (who are more likely to be girls than boys; McAnulty et al., 2001) are under 6 years of age, 25% are between 6 and 10 years old, and 50% are between 11 and 13 (Erickson, Walbeck, & Seely, 1988). People with pedophilia often say that they believe that adult sexual contact with children has positive effects for the child. Compared to rapists, people with pedophilia who have molested children view themselves as less responsible for the abuse and view the child as more responsible (Stermac & Segal, 1989)—claiming that the child “seduced” them. In fact, some child molesters with pedophilia report that they didn’t think they were harming the children they molested, but were “sharing pleasure” (Spitzer et al., 2002). Studies suggest that men with pedophilia who are sex offenders are likely to have at least one other paraphilia (Heil & Simons, 2008; Raymond et al., 1999).

Pedophilia often begins in adolescence, and it tends to be a chronic condition. The relapse rate for pedophiles drawn to boys is twice that of those drawn to girls (American Psychiatric Association, 2000). Although pedophilia typically involves sexual behavior with a minor, the disorder may be limited to fantasies, viewing pornography, or voyeurism directed toward minors.

Note that not all sexual abuse of children occurs because of a consistent sexual arousal pattern: Children may be sexually abused because the abuser has another sort of psychological disorder, such as a substance abuse problem (often alcohol, which as we saw in Chapter 9 can disinhibit behavior), or the sexual abuse is an act of aggression (Dorr, 1998; Fagan et al., 2002; Marshall, 1997). (The effects of child sexual abuse and other forms of child maltreatment are discussed in Chapter 2.)

Sexual Sadism and Sexual Masochism: Pain and Humiliation

Sexual sadism and sexual masochism are two complementary sides of a mode of sexual interaction in which pain, suffering, or humiliation creates or enhances sexual excitement. People who do not experience significant distress or interpersonal problems because of their sadistic or masochistic sexual fantasies, urges, and behavior and whose sexual partners are consenting adults would not be diagnosed with either of these disorders. Let’s examine the DSM-IV-TR criteria for these two disorders.

Sexual Sadism: Inflicting the Pain
